AUTHORS

A

- Adams, F D and Mallory, Tracy B—Acute Anterior Polymyositis Bulbar Type Case 21362 494
 Agranulocytic Angina. Case 21372 539
 Lymphoblastoma. Aleukemic Leukemic Type Case 21352 427
 Lymphoblastoma of the Thymus (Thymoma) with Pulmonary Infiltration. Case 21412 726
 Albright F Holmes G W Bock A V Jacobson B M and Mallory Tracy B—Plasma Cell Myeloma, Diffuse Case 21271 26
 Ludwig A O, Holmes G W and Mallory Tracy B—Chronic Amyloid Nephrosis with Contracted Kidneys Case 21462 987
 Allen Anna M—A Review of the Varieties of Polyps Which Have Caused Death in the Massachusetts State Hospitals For Mental Disease (M L S.) 1013
 Allen, A W Castleman B and McKittrick L S—Tuberculosis of Colon and Bladder Case 21311 232
 Daland, E M Kubik, C S and Mallory Tracy B—Adenocarcinoma of the Uterus with Infiltration of the Rectal Wall Case 21439 3-7
 McKittrick L S and Castleman B—Ameloblastic Granuloma of the Cecum Case 21312 235
 Altschul Mark D and Darow Harry A—Malignant Hypertension (Or) 951
 Anderson Gaylord W—The Present Status of Scarlet Fever Prevention (M M S.) 203
 Anderson George E and Eschweiler, Paul C—Diet Control (B R) 786
 Anspach, Brooks M—Gynecology (B R) 85
 Archer, Benjamin H—Specific and Nonspecific Arthritis (With Special Reference to Trauma) (Or) 709
 Arnison W D and Turner G Grey—The Newcomer Upon Tyro School of Medicine 1831-1931 (B R.) 42
 Atchley Dana W—The Role of Peripheral Circulatory Failure in Clinical Medicine (Or) 861
 Augustine, Donald L. and Spink Wesley W—Trichinosis in Boston (Or) 527
 Ayar James B and Mixer William Jason—Herniation or Rupture of the Intervertebral Disc Into the Spinal Canal (Or) 385
 Ayers Charles E—Further Case Studies of Lumbosacral Pathology with Consideration of the Involvement of the Intervertebral Discs and the Articular Facets (Or) 716

B

- Baker M P Mallory Tracy B and Bauer W—Nephrosclerosis Malignant Type Case 21351 424
 Richardson, W Means, J H and Mallory Tracy B—Subacute Glomerulonephritis Case 21471 1030
 Bakst, Henry J—Mycotic Infection of the Lungs in the Differential Diagnosis of Pulmonary Tuberculosis (M M S.) 1177
 Baldrige Robert R—A Case of Congenital Hypertrophy of the Vermontanum (N E U A) 46
 Ball C F—The Irradiation Treatment of Tumors Late European Developments (V S M B) 467
 Ballou Harry C Graham Evaris A and Singer Jacob J—Surgical Diseases of the Chest (B R.) 596
 Banister H—Psychology and Health (B R) 86

- Barnbour Ellen H—Adjustments During Four Years of Patients Handicapped by Polymyositis (Or) 563
 Barnes J Arthur and Richmond, Eugene L—Hyperinsulinism (Or) 225
 Barney, J Dellinger—Personal Experiences with Tumor of the Bladder (N E S S) 976
 Bartlett, M K and Mallory, Tracy B—Adenocarcinoma of the Ileocecal Valve With a Metastasis to the Liver Case 21342 377
 Mosher H P and Mallory Tracy B—Carcinoma of the Throid. Case 21482 1097
 Bauer W Baker M P and Mallory Tracy B—Nephrosclerosis Malignant Type Case 21351 424
 Mallory Tracy B and Short C L—Aplastic Anemia (Benzol Poisoning) Case 21301 183
 Baumgartner, Leona—Edwin Klebs A Centennial Note (Or) 60
 Bellerose Maurice N—Low Back Pain Caused by Lumbosacral Abnormalities (V S M S) 177
 Bennett, Theodore—Case Report. Bronchial Asthma Due to Paper Sensitivity (Or) 121
 Bierman, William and Schwarzschild Myron—The Therapeutic Use of Short Wave Currents (M M S.) 509
 Binet, Léon—Leçons de Physiologie Médico-Chirurgicale (B R.) 750
 Six Conférences de Physiologie (B R.) 592
 Blake G White P D, Mallory Tracy B and McGinn Sylvester—Coronary Thrombosis with Occlusion Fresh Case 21522 1315
 Blumel, C S—Stammering and Allied Disorders (B R.) 87
 Bock A V Jacobson B M Mallory Tracy B, Albright, F and Holmes G W—Plasma Cell Myeloma, Diffuse Case 21271 26
 Mallory Tracy B, Holmes G W Richardson W and Jacobson B M—Lymphoblastoma, ? Giant Follicular Type with Involvement of the Spleen Kidney Bone Marrow and Lymph Glands Case 21281 67
 Boos, William F and Werby A Benjamin—Arsenic in Human Tissues and Food Animals I So-Called Normal Arsenic. (M L S.) 520
 Bowers Walter P—The Massachusetts Board of Registration in Medicine. (Or) 1
 Bowman Karl M—Progress in Psychiatry for 1934 (M P) 63
 And Howard Paul M—Report of a Case of Lead Encephalitis Due to Tri Ethyl Lead (Or) 559
 Breed William B and Castleman Benjamin—Adenocarcinoma of the Tail of the Pancreas with Metastases to the Peritoneum Pelvis Uterus Liver Diaphragm Mesenterio and Retroperitoneal Glands Lung and Pleura. Case 21461 682
 Chronic Ulcerative Colitis Case 21332 827
 And Mallory Tracy B—Acute Rheumatic Fever Case 21392 626
 Coronary Thrombosis Case 21423 776
 Bridges, Milton A—Food and Beverage Analyses. (B R) 956
 Brodny M L and Prather George C—A Ray and Autopsy Study of Anatomical Changes of the Upper Urinary Tract in Patients with Obstructing Prostates (M M S.) 457
 Brown Lawson—A Record Book for Tuberculosis Patients (B R.) 785
 Bryce Alexander—Ideal Health or the Laws of Life and Health (B R.) 444
 Buehler E. C—Free Medical Care (Socialized Medicine) (B R.) 1158

- Burnett, Francis Lowell—The Progress of Nutrition (M P) 480
 Burrige, W—Alcohol and Anaesthesia (B R) 338

C

- Cabot, Hugh—(See "The Doctor's Bill") (E) 188
 Cabot, R C, Means, J H, White, P D, Kranes, A, Kubik, C S, Mallory, Tracy B and others—Bacterial Endocarditis, Acute (? Hemolytic Streptococcus), Aortic, Mitral and Tricuspid Case 21451 925
 Campbell, Fred L—Some Hints Aiding in the Diagnosis of Anterior Poliomyelitis before the Paralytic Stage (C) 383
 Cargill, F V—An Appeal for Data to Be Incorporated in the Directory of the American Medical Association (C) 439
 Carty, John R—Diagnostic Possibilities in Soft Tissue Radiography (M M S) 517
 Casey, John F—A Criticism of an Editorial on "Polio Vaccines" (C) 996
 Cass, J S, McKittrick, L W, Meigs, J V, Mallory, Tracy B, Miller, R H and Holmes, G W—Fibroma of Ovary Case 21411 723
 Castleman, B, Allen, A W and McKittrick, L S—Amebic Granuloma of the Cecum Case 21312 235
 And Breed, William B—Adenocarcinoma of the Tail of the Pancreas with Metastases to the Peritoneum, Pelvis, Uterus Liver Diaphragm Mesenteric and Retroperitoneal Glands, Lung and Pleura Case 21401 682
 Chronic Ulcerative Colitis Case 21332 327
 McKittrick, L S and Allen, A W—Tuberculosis of Colon and Ileum Case 21311 232
 Caughey, John Walton—Bernardo de Gálvez in Louisiana 1776-1783 (B R) 1273
 Chadwick, Henry D—A Handbook of Community Resources (C) 779
 Poliomyelitis Convalescent Serum (C) 36
 Chaffee, E L—The Physics of High Frequency Currents as Used in Medicine—Diathermy, Radiotherapy and the Electric Knife (M M S) 505
 Chapman, Earle M—The Phthalein Test of Kidney Function in Anemia (Or) 166
 Cheever, A W, Mallory, Tracy B, Eustis, R S and Higgins, H L—Congenital Syphilis—Case 21382 580
 Cheever, David—Methods and Results in the Surgical Treatment of Diseases of the Biliary Passages (M M S) 463
 Chideckel, Maurice—Female Sex Perversion (B R) 504
 Christian, Henry A—Expected Lags Between Clinical Diagnosis and X-Ray Confirmation (Or) 593
 Christie, A C—Economic Problems of Medicine (B R) 90
 Churchill, E D, Crone, N L P, Hampton, A O, Jones, C M, Richardson, Wyman and Mallory, Tracy B—Tuberculosis, Miliary, of the Lungs, Liver and Spleen Case 21452 929
 Holmes, G W, King, D S and Mallory, Tracy B—Carcinoma, Epidermoid, Bronchiogenic, Left Upper Lobe Case 21291 122
 Mallory, Tracy B, Jones, C M and Schatzki, R—Leiomyosarcoma of the Distal Third of the Esophagus with Extension into and Ulceration of the Mediastinal Lymph Nodes Case 21501 1194
 Chute, Richard—The Recurrence of Benign Obstructing Prostates Years After Prostatectomy (N E U A.) 55

- Clark, W Mansfield, R E Dyer and Others—The Harvey Lectures (B R) 194
 Clendening, Logan—Methods of Treatment (B R) 90
 Clow, Fred Ellsworth—Factors in the Management of Constipation (N H M S) 1187

NUMBER 1

EDUCATIONAL SYMPOSIUM

THE MASSACHUSETTS BOARD OF REGISTRATION IN MEDICINE

BY WALTER P. BOWERS, M.D.*

THE early history of medical practice in the American colonies shows that the better trained doctors were dissatisfied with the standing of a proportion of the physicians of that period. This led to movements designed to improve conditions relating to medicine for some persons have seemed to believe that there were more charlatans than educated physicians all through the years preceding the enactment of laws providing for the registration of doctors. Dr. Sigerist however, in his address before the Congress on Medical Education, Hospitals and Licensure, February 18, 1935 expressed a contrary opinion. However that may be the doctors in Massachusetts began the movement for the registration of physicians very early, as recorded by Dr. Reginald Heber Fitz in his presidential address before the Association of American Physicians, May 29 1894, and in the annual oration before the Massachusetts Medical Society, June 10, 1894.

The references are not quoted verbatim but only in substance because of the peculiar literary construction of the earlier periods.

Massachusetts led in attempts at reform in medical practice in this country, for in 1649 an act was passed designed to regulate the practice of churgeons, midwives, physicians and others which required of such practitioners conformity with the approved precepts of that day. In 1653 a petition to the "Honorable Court" asked to have it proceed to ascertain whether those who practice both physics and chirurgery to the hazarding of the lives and limbs and the detriment of many, being unskilled in those acts, be restrained until they be "exercised" by skilful and authorized physicians and chirurgeons, and these be approved and licensed by some magistrate. In 1737 arguments were submitted to the local medical society in Boston (founded in 1735 or 1736) in favor of regulating the practice of medicine through examination of a board of physicians. In 1781, when the Massachusetts Medical Society was incorporated, authority was conferred on this body to issue certificates of ap-

proval of such as were found competent to practice medicine. These were designated as licensed. In 1789 1803 and 1819 amendments to the charter of the Massachusetts Medical Society were adopted, one of which gave to licensed physicians the right to recover at law for services rendered and deprived the unlicensed doctors of this advantage.

Soon after the incorporation of the Massachusetts Medical Society medical graduates of Harvard were made licentiates and in 1837 similar authority was given to the Berkshire Medical Institution.

In none of the various acts however was there any provision for the prevention of any one not thus licensed to practice medicine so that quackery continued to flourish. In 1859 the Legislature rescinded all laws relating to the licensing of physicians and for the succeeding thirty five years no laws were passed relating to the practice of medicine in this Commonwealth, although the leading men in the Massachusetts Medical Society strove diligently to secure the enactment of appropriate bills. These efforts were blocked by the opposition of low grade practitioners aided and abetted by men prominent in public life who claimed that restrictive laws invaded personal liberty and created a favored class.

Thomsonianism seemed more popular in the early stages of this period than regular medicine. This phase of prejudice and credulity was so general, that a full recital of its history would require a volume of considerable size.

Meantime, a general sentiment among doctors throughout the Union was favorable to the regulation of medical practice and this led to the adoption of laws governing the registration of physicians in most of the states. Massachusetts, however, was among the last to take this important step.

The example of the more progressive states spurred the profession in our Commonwealth to vigorous action, designed to interest the people in the importance of raising the standards of medical education and practice.

The effective step which led to the passage of the act creating the Board of Registration in Medicine in Massachusetts was the appoint-

Bowers, Walter P.—Managing Editor, New England Journal of Medicine. For record and address of author see "This Week's Issue" page 32.

ment of a committee of eighteen by the Massachusetts Medical Society under the chairmanship of Dr G J Townsend of South Natick. This committee was strengthened by the addition of Drs George C Shattuck, B E Cotting, George H Lyman, H W Williams and Alfred Hosmer. The work of this committee consolidated and activated sentiment in the Society which was further roused by Dr R H Fitz, Dr George W Gay and Dr Edwin B Harvey. It will thus be seen that the stage was set for a successful attempt to bring Massachusetts into line with her sister states, especially so because Dr Harvey was, in 1894, a member of the State Senate. In association with the committee, Dr Harvey drafted a bill and worked diligently for its passage against bitter opposition, the character of which was described in the *New England Gazette* as follows:

"What a collection of them there was in the Green-room at first and afterwards in the large hall of the House of Representatives to which an adjournment was necessary on account of the crowds! Medical blacklegs of all kinds, deceitful clairvoyants, long-haired spiritualists, necromancers, wizards, witches, seers, magnetic healers, pain charmers, big Indian and Negro doctors, abortionists, harpies who excite the fears and prey on the indiscretions of the young of both sexes, who treat venereal diseases with the utmost secrecy and dispatch, who have good facilities for providing comfortable board for females suffering from any irregularity or obstruction, who sell pills which they are particular to caution patients when pregnant against using, *et id genus omne*. Some of them looked sleek, well fed and prosperous, others seemed to have come from the slums of destruction. Most of them had a coarse animal degraded look."

The bill was enacted only after several redrafts which, in the last one, provided for the exemption of certain forms of practice in the following words:

"This act shall not apply to commissioned officers of the United States Army, Navy or Marine Hospital Service, or to physicians or surgeons called from another state to treat a particular case, nor to clairvoyants, persons practicing hypnotism, magnetic healing, mind cure, massage methods, Christian Science, cosmopathic or any other method of healing, provided that such persons do not violate any provision of section ten of this act." Section ten provided that "whoever not being registered"

"shall advertise or hold himself out to the public as a physician or surgeon" "by appending to his name the letters M D or using the title doctor, meaning thereby a doctor of medicine, shall be punished," etc. That is, these several defined cultists could not legally practice medicine after the passage of the act.

The Board of Registration in Medicine came into being in July 1894 by the appointment by his Excellency, Frederick T Greenhalge, of Edward Jacob Forster of Boston, Augustus L Chase of Randolph, Daniel B Whittier of Fitchburg, Walter P Bowers of Clinton, Stephen H Blodgett of Cambridge, C Edwin Miles of Boston and Augustus C Walker of Greenfield. Dr Blodgett almost immediately resigned and his place was filled by the appointment of William C Cutler of Chelsea.

The Massachusetts Medical Society was represented by Drs Forster, Walker and Bowers, the State Homeopathic Society by Drs Whittier and Cutler and the State Eclectic Society by Drs Chase and Miles. The law provided that "no member of the board shall belong to the faculty of any medical college or university and not more than three members shall at any one time be members of any one chartered medical society." These restrictions still exist.

The board was duly organized July 10, 1894 with the choice of Dr C Edwin Miles, Chairman, and Dr Edward J Forster, secretary, and proceeded to register physicians as specified in the act with five designations:

- A To graduates of legally chartered medical colleges or universities having the power to confer degrees in medicine who were practicing medicine in this Commonwealth, July 10, 1894
- B To those who had been practitioners of medicine in this Commonwealth continuously for a period of three years next prior to June 7, 1894
- C To graduates of legally chartered medical schools or universities having power to confer degrees in medicine in this Commonwealth thereby being exempt from examination up to January 1, 1895
- D To graduates examined by the board
- E To non graduates examined by the board

The law provided a diagnet which swept into recognition a large number who were not educated physicians as classified under B and until 1915, the board continued to register applicants who could pass the examinations even though not possessed of a medical degree. Even though these earlier examinations were certainly elementary in character, a considerable proportion of applicants who came under the examination clause were rejected.

In reports of the board, subsequently submitted, repeated explanations were made, that the conditions relating to medical practice in Massachusetts were not satisfactory, in that complaints of irregular practice reported to police departments were not always followed by prosecutions and recommendations to the Legislature for changes which would tend to promote

protection of the people from incompetent or unscrupulous practitioners did not receive adequate attention. An amendment modifying section ten relating to the definition as to who might practice medicine was enacted May 10, 1895 and helped to clarify that situation relating to who could or could not practice medicine.

Since osteopaths were not included in the exempted classes and complaints were made that they were practicing medicine, they sought inclusion among the other cults and were successful in the passage of an amendment to the law. This was followed by the appointment of an osteopath to the board in 1907 and further recognition of this cult was taken by the Legislature in 1909 by an act which provided for the registration of osteopaths under two classifications in substance:

- 1 Any person who had been in active practice in this Commonwealth prior to January 1, 1909 and was a graduate of a school or college of osteopathy giving certain specified courses
- 2 Those who had practiced osteopathy in this Commonwealth for four years prior to the passage of the act

Such registrants were not allowed to prescribe or administer drugs for internal use or perform major surgical operations or engage in the practice of obstetrics. In this act, the Legislature decreed that the practice of Osteopathy is the practice of medicine. This had also been the decision of the Supreme Court in a case that went up on an appeal. As heretofore osteopaths in common with other applicants could register under the regular procedure of examination because no requirement for a medical education had been adopted.

In 1910, at the time of the establishment of a Board of Registration of Nurses, the clerical functions of the boards of medicine and nurses were carried on in the same office, and the secretary of the medical board became ex-officio secretary of the nursing board.

About this time, chiropractors engaged the attention of the board and in 1914 eight were convicted of practicing medicine without being registered. This cult has been striving for state recognition ever since, even going so far as to attempt the establishment of a chiropractic school. This effort was frustrated in 1915 when a student sought to qualify for examination under a certificate of attendance from the New England College of Chiropractic located in Boston. Unfavorable court action followed and this institution folded its tent and silently stole away. In this year (1915) an important amendment to the medical registration law was enacted which provided that applicants for registration must show the possession of the degree of doctor of medicine or its equivalent from a legally chartered medical school having the power to confer degrees in medicine. This in-

cluded osteopathy under the decree of the Legislature.

Encouraged by this modest addition to the law, the Board of Registration petitioned for further requirements and in 1917 the specified time given to teaching medicine was defined as thirty six weeks in each year of a full four years' course. This was changed in 1933 to thirty two weeks, with more definite specifications of the time covered each year. Meantime, in 1922 the Legislature was persuaded to require of applicants for registration a premedical course equivalent to that required for graduation from a public high school and even only this after twenty seven years of continuous appeals to the Legislature for a law which would give reasonable assurance of average premedical experience of applicants for registration. No changes relating to premedical or medical education have been incorporated in the law since that time except that relating to the number of weeks required for a medical education as stated above.

At the present time forty state medical examining boards demand of applicants, graduation from medical schools which require two years of college work, four one year of college work and five require only a premedical training in high school courses. These last are Delaware, Missouri, Nebraska, Ohio and Massachusetts, but all except Massachusetts, have the power to demand of applicants, graduation from medical schools which are "accredited" or "reputable" or "approved" or "in good standing", that is, these boards can accept or reject candidates according to their estimates of the efficiency of each college from which applicants apply for examination. Massachusetts is alone in having no right to determine anything relating to the quality of instruction in medical schools but must accept for examination all who are graduates of chartered medical schools which give courses covering four years of thirty two weeks in each year. She stands in the lowest position in this regard in the United States.

Other amendments to the law provided for protection to medical students and hospital interns through limited registration because of a threat by enemies of the board to bring action against these men for practicing medicine without being registered. Certain other changes were made from time to time in order to give the board power to deal with various irregularities in medical practice.

The administration of the law to register chiropropodists was also assigned to the Board of Registration in Medicine. In 1924 authority was conferred to register the diplomates of the National Board without examination. The number so registered up to April 1935 is 239. This practice has been adopted by forty two states and three territories. There is an inconsistency in this, in that Massachusetts adopts the standards of an organization of which it is no or

game part, but will not allow its board to accept standards of other reputable evaluating organizations. In other words, this Commonwealth does not have any concern respecting the standing of medical schools and depends on the Board of Registration to determine the qualifications of candidates for licensure by an examination. The consensus among those regarded as authorities in medical education is, that such examinations by state boards, as are feasible under the Massachusetts law, do not prevent the registration of some unworthy applicants. Furthermore the most effective way to insure the training of qualified physicians is to control the source of supply.

Since the examinations, conducted by the board, seem to be its chief function relating to medical education and the prevention of incompetent medical practice, a detailed statement of the standing of out-of-state medical schools is not especially important, for there are only a very few unclassified medical colleges besides the osteopathic schools which are applying to our board for recognition. A slight change in our law would clarify this situation.

With the evolutionary changes in medical education which took place in this country in the early years of this century when we had about twice the number of medical schools as at present only a few of the unapproved schools are now able to carry on. The problem is how to bring them to a position of respectability or, if hopeless, how they may be eliminated. The facts should be faced.

In the early years of medical registration in this state the examinations were as elementary as the list of subjects employed. Written questions in the field of surgery, physiology, pathology, obstetrics and the practice of medicine covered the subjects. The list has been extended from time to time and now includes anatomy, histology, bacteriology, gynecology, diagnosis and therapeutics, pediatrics, toxicology, psychiatry, biology, chemistry, physics, and hygiene. It is probably impracticable to test the knowledge of applicants for examination in all of these subjects to a satisfactory degree under the present conditions, for it would mean a larger board and the expenditure of time beyond that at the disposal of busy practitioners. In addition, it is unlikely that the state would appropriate the necessary money, for appeals for larger appropriations have not met cordial responses although the revenue derived from the board's activities has contributed to the state treasury nearly forty-five thousand dollars in excess of its expenditures. Hence, it seems probable that the present system will have to be continued until other amendments will have been adopted.

The wide disparity in the comparative figures shown in the records of the rating of graduates of approved and non approved schools is significant.

The changes in subsequent years show improvement in the rating of graduates from approved schools, but no appreciable changes in the non approved schools. This last statement is confirmed by an analysis of the figures pertaining to eighteen years of results of examinations of the three unapproved schools in Massachusetts previous to 1934. Of graduates of one such school, the percentage of failures was 58+, of graduates of a second school, 54+, and of representatives of a third school 64+. With the added years another fact is significant in that the number of repeaters is growing and from non approved schools in a recent examination, 88 were thus designated. All of these facts tend to show that the probability of these non approved schools ever emerging from this class is unlikely, unless taken in charge by groups of persons of requisite ability and with adequate financial resources.

SUMMARY

This brief history of the Massachusetts Board of Registration in Medicine will convey an inadequate record of its accomplishments.

It was created in response to the efforts of organized medicine in this state over bitter opposition. The intent of its sponsors was to protect the people from evident improper and dangerous forms of medical practice. It has made only a partial success of this expectation because of hostility from within and outside of the profession. The original law was defective but was better than none. The Legislature has been persuaded to make certain changes which have added to the power of the board in dealing with criminal and unethical practices. The board has taken advantage of all powers conferred in the revocation and suspension of licenses in appropriate cases. It has consistently and persistently tried to raise the standards of medical education and service.

In the beginning it took away the right to practice of 618 persons who tried to qualify under the liberal provisions of the initial law, and under its examinations has on many occasions refused to license over fifty per cent of applicants for registration. For nearly twenty years it had to examine all comers who cared to apply regardless of their qualifications. It succeeded in 1915, in the passage of an act, in securing the requirement that only those possessed of an M.D. degree or its equivalent, would be accepted for examination, and later had amendments added defining the time and certain premedical studies which medical schools must observe in which applicants for registration have acquired their medical training.

Several other changes were for the protection of medical students and hospital internes. When the board began to function there were only three medical schools in this state. There are now six, three recognized and three unrecognized by the Council on Medical Education.

and Hospitals. The graduates of these unclassified schools now suffer most in the examinations conducted by the board, and the rejected candidates furnish a very large proportion of the repeaters. Furthermore it is largely the opposition of representatives of these three substandard schools which has prevented progress in raising the standard of medical education in this state so that Massachusetts stands with a wide open door to welcome all who are graduates of chartered medical schools, regardless of their standing. Its requirements in this respect are inferior to all of the other states of the Union.

His Excellency, Governor Curlov, in his inaugural address last January said, "The Commonwealth of Massachusetts has always maintained an enlightened interest in matters pertaining to the health of the citizens." This is true of many of its citizens and institutions dealing

with the health of the people but is not true of its Legislature in certain particulars.

The immediate question of most importance is how long will Massachusetts claim to maintain "an enlightened interest in matters pertaining to the health of its citizens"?

The quality of medical practice reflects in a large degree the quality of instruction given by schools that train doctors. In order to bring about improvement in dealing with individual illness and to promote public health, it will be necessary to attack the problem at its source, that is, the medical school.

The Board of Registration has given loyal service to the state and should be accorded cordial cooperation. Its members have sacrificed their personal interests in giving freely of their time. Future progress will depend on a general demand for better laws.

THE VALUE OF THE MEDICAL LIBRARY IN MEDICAL EDUCATION

BY LINCOLN DAVIS, M.D.*

THE value of the medical library to the medical student, the practising doctor, and the community has been emphasized over and over again and is, I think, very generally recognized in principle. Sir William Osler and other medical leaders have eloquently and often discoursed on this theme. We must remember however, that a new generation is continuously replacing the old and that old truths must be repeatedly restated although at the inevitable discount at

tending the display of second hand goods. The outstanding feature of the adequate library is that there the original sources of information may be found, the student or practitioner who is unacquainted with the benefits of the library habit is urged as a starter to peruse the addresses by Oliver Wendell Holmes, William Osler, George A. Vincent, and Harvey Cushing on that subject.

Let me quote from a few of the maxims of these bibliophiles.

"Our American atmosphere is vocal with the flippant loquacity of half knowledge.

Davis, Lincoln—President Boston Medical Library. For record and address of author see "This Week's Issue," p. 22.

Half knowledge dreads nothing but whole knowledge" O W Holmes in 1878

William Osler exhorts us in making use of the library to "cultivate the critical investigating faculty. Get closer to the great minds of the race."

Dr Vincent aptly calls the library the "social memory."

Harvey Cushing has said that the soul of an institution of learning resides in its library. One of the world's earliest and most famous libraries was that at Thebes in the time of Rameses II. It was said by Silius to bear the inscription "Dispensary of the Soul."

Breasted tells us that the oldest known scientific document is a surgical treatise known as the Edwin Smith Papyrus written during the Pyramid age, perhaps by Imhotep himself. The surviving copy written in the 17th century B C although incomplete is well preserved, a priceless treasure brought to light by American research.

The respect and esteem in which the record of the written word has been held from the earliest times are shown by the large number of authentic manuscripts copied and transcribed from the classical periods of Greece and Rome, which have survived the vicissitudes of a turbulent history.

The confusion of historians concerning the calamitous destruction of the famous libraries of Alexandria variously ascribed to the accidental spreading of the fires set by the soldiers of Julius Caesar, and two centuries later to the harsh orders of the Emperor Aurelian, still later to the fanatical excesses of the Christians in carrying out the edict of Theodosius, and finally in 640 A D to the fury of the conquering Moslems under the Caliph Omar, is no doubt due in part to the desire to shift upon the other fellow the responsibility for a reprehensible act. In our own time something of the same kind is seen in the controversy as to the destruction of the Louvain library.

America is essentially library minded. Every respectable township has its general library so often the gift of some prosperous and loyal native son. Fine medical libraries exist in most of the principal cities. The splendid Surgeon General's Library extends a helping hand to every lesser medical or general library in the land, through its liberal policy of inter-library loans. The great national medical and surgical societies maintain reference libraries which furnish valuable assistance to their members. The medical schools have either libraries of their own or access to large urban medical libraries.

Massachusetts is preeminently equipped with facilities for consulting the literature of medicine. Our principal medical schools have splendid library facilities, the larger hospitals maintain adequate working libraries, and some of the larger cities have special medical collections. The Boston Medical Library with one of the

best medical collections in the country maintains a reading room open to all practitioners and students, with a system of inter-library loans which makes its books available to physicians wherever located. Our medical library resources are certainly ample. How about their use?

The average busy practitioner engrossed with the care of the sick and faced with the serious problem of earning his daily bread finds little time for reading. If he takes a medical journal or two and occasionally glances at them he feels that he is doing all that can be expected of him in keeping up with medical literature. He seldom enters a library. The equally busy but more ambitious man who attends medical meetings and occasionally prepares papers for presentation before them, may have the library brought to him through the services of the national library bureaus which furnish bibliographies, references, abstracts, translations, and packets of reprints, on almost every subject. "Complete research service at a reasonable charge." I do not question the value of this service if used by one who knows enough to know how much to use it. I do believe it encourages the production of a good many articles whose chief value is in their imposing bibliographies.

The doctor should have learned how to use a medical library while he was a medical student. He should have learned how to dig out the references himself and get at the original sources. Of course, if unfamiliar with some foreign language he must rely on a translation, but he should make his own abstracts and see with his own eyes every article quoted.

I believe it is now a part of the curriculum of most schools to require students to familiarize themselves with the technique of literary research. The reduction in the number of lectures and the increase of free time permit of independent reading. In a few advanced schools, courses are offered in the history of medicine and students are given an insight into the alluring field of classical medical literature. Familiarity with original sources is cultivated and the seed of literary scholarship is planted in those capable of germinating it. A student so educated will always come back to the library at every available opportunity in after years with real affection and with the knowledge of how to use his time to the best advantage.

Furthermore, he will be inclined to make time to do so. He is in a position to appraise scientific literature and discriminate between what is sound and reliable and what is not. He can go straight to original sources and will readily detect padded bibliographies.

Recently, in accordance with the trend of the times toward making learning easy and in the laudable endeavor to make available to the student classic medical texts, selected excerpts from

famous writings in medicine and the allied sciences have been published. These collections are of distinct value for ready reference and serve to stimulate deeper reading on the part of the student, but excerpts, and especially abstracts divorced from their context, are apt to give a somewhat distorted view and, unfortunately, in one or two instances at least inaccuracies have crept in which make reference to the originals more than ever necessary.

If advice might be ventured by one who does not pretend to have followed his own precepts I would say to the practitioners of medicine and surgery, go to your medical library in person and cultivate the habit of using it. If you do not know how, learn how. There are young librarians always eager to show the way. If you have not time, make a little time. Keep in touch with the world's progress as set forth in the current periodicals. Do not neglect the foreign periodicals, especially those in your own specialty. Look over the new books and occasionally glance at an old one. The library furnishes a liberal and inexpensive postgraduate course to its inmates.

To the young man starting on his career no matter where or in what circumstances I would say subscribe to two or three of the best periodicals

and do not let a single number get by you. Keep a card catalogue of articles which arouse your interest. At an early stage select some subject, never mind how minute, trivial or obscure—from earrots and the common cold, or the growth of the finger nails, to the interactions of the hormones of the ductless glands and keep abreast of all progress in your subject. Be an authority on the literature at least. This may be an encouragement of faddism perhaps but honest finds tempered by common sense do no harm and sometimes lead to real achievement. Visit your neighborhood medical library at regular intervals and check up on your progress. Familiarity with the work of others may suggest ways in which you can do a little worth while clinical research of your own.

Recently the Japanese surgeon Kyusaku Ogino made some simple observations on the ovulation of the human ovary which have changed the whole aspect of the physiology of conception. Any one of ten thousand operating surgeons in this country might have made such observations, if he had had the vision. In a select few vision may be innate for the majority it must be developed by reading, study and thought.

THE COMMUNITY HOSPITAL AS A CENTER OF POSTGRADUATE EDUCATION

BY JOSEPH H. PRATT, M.D.*

IN many ways the development of the rural hospital has advanced medical knowledge among the physicians within reach of its influence. The standards set up by the American College of Surgeons and the American Medical Association have been of help in improving the quality of the work of small hospitals, although only 15 per cent of these meet the requirements.

In discussing the subject of graduate training in medicine there is possibly a tendency to lay too much stress on the ways and means of furnishing instruction and too little on the attitude of the physicians whom the national and state organizations wish to have instructed. To be successful some thirst for knowledge and willingness to work must exist in the minds of the members of the staff of the small hospital and in those of the physicians in the surrounding countryside. Unless the local men wish to increase their knowledge by study the best methods will fail. Of the man who knows it all and for this reason does not attend the meetings of his county and state societies nothing can be expected. They are a waste of time, he says and he feels better at home and perhaps says Osler, "that is the best place for a man

who has reached this stage of intellectual stagnation."

The word student it may be recalled comes from the Latin word *studere* meaning to be eager, zealous or diligent. When these qualities are lacking spoon feeding is always desired but this is as poor a method of mental nurture for graduates as undergraduates. Now it is unfortunately true that lack of energy is a characteristic of advancing years. With youth behind us it is increasingly difficult to make sacrifices for the sake of knowledge, our minds like our bodies at a certain age become fixed (Jowett). Fortunately a few keep up their interest in acquiring knowledge throughout life. It is these rare minds that sometimes are able to leaven the dough in which they find themselves. To take an outstanding example consider what a stimulus James Mackenzie must have been to his colleagues in the provincial city of Barnley during his long career there as a general practitioner, that is if they were able to catch a little of his enthusiasm and zeal for the truth. At all times "many are the wand bearers and few are the mystics." Sir James Mackenzie himself felt that his influence was slight until the publication of his book on the pulse attracted attention in Germany and America to

*Pratt, Joseph H.—Physician-in-Chief, New England Medical Center. For record and address of author see "This Week's" page 22.

his work. In his own country it aroused little interest. He told me that during a period of fifteen years he read papers in Manchester, the medical center of Lancashire, detailing his observations and discoveries and not one of them drew forth any discussion.

In dealing with the subject of graduate medical education it seems that we should be content to provide practising physicians in the country with facilities for acquiring knowledge and not to be discouraged if the percentage of practitioners is small that takes advantage of them.

Measures for increasing the knowledge of practising physicians in diagnosis and treatment have multiplied in New England within the past decade. During the last two years in Massachusetts regular graduate courses have been given under the auspices of the Massachusetts Medical Society throughout the state. They have been admirably organized and well attended. The Connecticut Medical Society now gives a clinical course of graduate instruction at New Haven each fall lasting several days. Leading teachers from Boston, New York, Philadelphia, and other medical centers give instruction in addition to members of the Connecticut Medical Society. Some hospitals in neighboring states have offered attractive clinics. For example the Central Maine General Hospital at Lewiston provides an all day session every month or so for practitioners. Some of the leading specialists in Boston have given clinics in this series and the attendance has been large and enthusiastic.

Fellowships paying an adequate stipend have been established in Massachusetts by the Commonwealth Fund of New York so that rural practitioners in this state are able to come to Boston for a month or more of study. The Bingham Associates Fund for the Advancement of Rural Medicine has given fellowships to practitioners in Maine for a period of study at the Medical Clinic of the New England Medical Center in Boston. These fellowships are available for from one to four months.

Within recent years facilities for diagnosis have been enlarged in the hospitals throughout New England by installing modern x-ray apparatus and equipping clinical laboratories under the charge of well-trained technicians. The chief hospitals in the larger cities employ full time pathologists. Many hospitals in the smaller cities within a range of fifty miles from Boston have visiting pathologists who are connected with the pathological departments of Harvard, Tufts and Boston University. In these hospitals the number of autopsies is increasing. In a recent month in a hospital ten miles from Boston autopsies were made on 100 per cent of the fatal cases.

Probably autopsies performed by able pathologists offer the soundest method of instruc-

tion that can be given in any hospital and are of the greatest value to those who have studied the cases during life. "Pathology is the basis of all true instruction in practical medicine" (Wilks). This was the motto Dr Osler selected for the title page of the first pathological report from the Montreal General Hospital. It was the guiding principle in his own education. "Problems in physiology and pathology," Osler said "touch at every point the commonest affection, and through exercise in these the man is chastened, so to speak, and can never, even in the daily round of the most exacting practice, degenerate into a money-making machine."

In his address on the Educational Value of the Medical Society Osler emphasized the importance of the demonstration of instructive specimens in morbid anatomy. "After all has been done many cases of great obscurity in our daily rounds remain obscure, and as post mortems are few and far between, the private practitioner is at a great disadvantage, since his mistakes in diagnosis are less often corrected than those of hospital physicians. No more instructive work is possible than carefully demonstrated specimens illustrating disturbance of function and explanatory of the clinical symptoms" (Osler). Next to the patient himself the hospital pathologist is the best teacher in the rural hospitals.

Staff meetings at which clinical cases are demonstrated can be of great educational value. The minimum requirements of the American College of Surgeons include a staff meeting to be held at least once a month. Members of the Staff are instructed "to review and analyze at regular intervals their clinical experience in the various departments of the hospital, such as medicine, obstetrics and the other specialties, the clinical records of patients free and pay, to be the bases for such review and analyses." The presentation of instructive cases by the physicians who have studied them adds interest and value to these conferences. Ingenuity should be exercised to make the meetings profitable. Dr Ochsner of New Orleans suggests four methods of assuring a thorough review of the clinical work at the staff conference of which the following two seem especially commendable.

"1. A week before the meeting abstracts of the cases are given to two members of the Staff, neither of whom has seen the case and whose only interest in it is scientific. These two persons open the discussion and this is followed by general comment, without any reference to the attending physician. Laboratory findings are presented, including the report on the pathology which is given by the pathologist himself. The discussion is closed by the chairman who reads a summary of the case, including the final diagnosis and treatment."

"2 The facts concerning the cases are presented by the physician in charge without any mention of the ultimate findings, the final diagnosis, or the treatment, and then general discussion takes place. With this method the staff is more apt to discuss the case impartially because being unaware of the ultimate findings, they cannot be accused of destructive criticism. After general comments by staff members the remaining details including operative and necropsy findings are presented by the attending physician."

Whenever possible the pathologist should show the gross and microscopic specimens. If the meetings are to be helpful those present must express their opinions freely even when they vary from those of the physician in charge of the case. When freedom of discussion is absent the meeting may be a means of disseminating error rather than truth and it will certainly fail to be inspiring. Not long ago, at a well attended staff meeting held in a suburban hospital, a physician reported a case of sudden death occurring in a patient under his care in the hospital as doubtless due to cerebral hemorrhage. There was no autopsy. No one questioned the diagnosis. In fact there was no discussion. After the close of the meeting I asked the member of the staff who had invited me to be present if he thought none of the hospital physicians present knew that coronary disease and pulmonary embolism are the usual causes of sudden death. "Of course we know that," my friend replied, "but it would never have done to have disputed the old man's diagnosis. He would have regarded it as a personal affront." I am afraid such examples of unwillingness to speak the truth are not uncommon in staff conferences of other hospitals when autopsies are rarely obtained.

The fewer autopsies a physician sees on his own cases the more confident he is in the correctness of his diagnoses. There was truth in Osler's comment that morbid anatomy enables the physician "to correct his mistakes and if he reads its lesson aright may serve to keep him humble."

The importance of the hospital library in education should be stressed. The leading weekly and monthly journals should be taken and new books purchased. If each member of the staff contributes to its maintenance as he should, he will be more apt to take pride in the library and to use it, and his self sacrifice if he has made any, will do him good.

The Commonwealth Fund has sponsored six first class rural hospitals in different parts of the country for educational purposes. One of these is the Franklin County Hospital in Farmington, Maine. In the adjoining county in the town of Rumford the Bingham Associates have added to the facilities of the excellent Community Hospital by paying the salary of a resi-

dent physician and providing a new x ray equipment, an electrocardiograph, basal metabolism machine, new operating table and some apparatus for the clinical laboratory. In addition a library of about 200 recent medical and surgical books was given to the hospital, and leading periodicals furnished.

Now means of diagnosis involving the use of instruments of precision are a hindrance rather than a help unless there is someone in a hospital who is skilled in their use and in the interpretation of the findings. Few clinicians have had as broad a knowledge of physiological and pathological chemistry as Friedrich v. Müller. Yet he is quoted by one of his pupils as having said that his percussion fingers are worth more to the practising physician than a whole chemical laboratory. There is certainly a tendency to overrate laboratory procedures and to underrate the importance of a careful history and a thorough physical examination. Often when asked in private practice to see patients in consultation the physician in charge has handed me a report of a urine or blood examination or an x ray examination with the implication that was all one needed to know about the case. A few years ago in making a visit with a physician in charge of the medical service of an exceptionally well equipped rural hospital, I was asked my opinion in a couple of cases. The first was one of pericarditis with effusion. Although the physical signs were typical they had not been detected. The diagnosis I learned had been made by the radiologist. Books were consulted and by some strange misreading of a standard text it was thought that to perform paracentesis the needle should be inserted just to the left of the sternum in the fourth or fifth interspace—exactly in the normal position of the internal mammary artery. A surgeon was called and he inserted a needle in the position just mentioned. Hemorrhage resulted and the patient collapsed. The second case was one of congestive heart failure, loss of weight, and rales over the upper lobe of the right lung in a young man. There had been a pleurisy with effusion a couple of months before admission. When I told the doctor it seemed to me to be a typical case of pulmonary tuberculosis he said that could not be the diagnosis as a guinea pig inoculated with the pleuritic fluid did not develop tuberculosis! The conclusion is justified that in these cases nothing was gained by having available an x ray machine and a bacteriological laboratory.

For the past three years members of the resident medical staff of the New England Medical Center have acted as residents at the Rumford Community Hospital for periods ranging from one to four months. They have made the examinations in all cases admitted to the hospital and have kept the records. As the men have had two to three years of hospital experi-

ence before going to Rumford they have been of more help to the hospital staff and to the patients than young graduates who had not served an internship would have been.

Bingham Fellowships offered to members of the visiting staff of the Rumford Hospital were accepted by nine out of the total of eleven physicians who are in attendance. These doctors when receiving graduate instruction all worked in the medical clinic of the Boston Dispensary where they took histories and made and recorded physical examinations under the supervision of one of the senior men of our staff. It was hoped that the educational value of personally examining patients and recording their findings would be so impressed upon these men that they would write good notes after resuming work in their own hospital.

The importance of careful case taking was possibly more appreciated a hundred years ago by the men who were establishing hospital services than it is by physicians similarly engaged today. Then the field of physical exploration had recently been opened up by the work of the French school especially Corvisart, Laennec and Louis. In 1811 when money was raised for the building of the Massachusetts General Hospital, Boston had a population of only 34,000. Conditions were in some respects comparable to those in many small cities today. The founders of the Hospital were two men then in the vigor of early middle life, James Jackson and John Collins Warren. They both realized the value of good hospital records. The case report of the first patient is still preserved. The painstaking penmanship indicates the importance attached to it. "It has long been my wish," wrote James Jackson, "to make the records of the hospital useful to the cause of science."

the observation of cases must be accurate and must be faithfully stated. If this is not done we shall be led into error, not to truth. It has been the practice at the Massachusetts General Hospital, in the medical department, to note the state of the patient every day, in acute cases as our records show. The records of Dr. Warren's hospital practice copied for his personal use filled six large folio volumes. The facts and observations contained in them furnished the basis for his work on tumors, the first monograph to be published on this subject. A reviewer of this volume describes the case reports as "clear, simple and graphic; they bear the unaffected impress of truth."

In planning graduate courses it is sometimes forgotten that "the bedside is always the true center of medical teaching." It has only been by observation of facts carefully recorded at the time and later analyzed that clinical medicine has made its advance, and this same method must be employed by every student if he is to educate himself. Speaking of his old master, Oliver Wendell Holmes says, "that to follow him in his morning visit was not only to take a lesson in the healing art, it was learning how to learn, how to move, how to look, how to feel, if that can be learned. To visit with Dr. Jackson was a medical education."

It is a question if much can be learned that is of lasting value from lectures or clinical demonstrations unless the information gained from them is made the starting point for personal work. When I entered Dr. Mall's anatomical laboratory as a student I was amazed to find that we were to have no lectures or demonstrations. "We demonstrate to ourselves from our own dissections," said a student and so we did. In his description of the anatomical course at the Johns Hopkins University, Mall said, "I believe that there is but one way to learn any subject, and that is through study. The very name student tells what the person so named should be doing. If we can make the student work thoroughly and carefully, a great result is achieved. It makes of him an artist, an actor, an expert, not a dilettante. He is upon the stage, not in the audience." This says Dr. Sabin was "Mall's fundamental contribution to education—the concept that self-education is the only form of lasting value, the inductive method with the student as actor."

In planning instruction for practitioners in clinical medicine should not an effort be made to make actors of them? Might it not be well if the visiting doctors who give graduate instruction in community hospitals adopted a rôle similar to that of a dramatic coach and taught the local men to put on their own show? By that I mean the working up and demonstration of their own cases with general comments based on a study of the recent literature dealing with the disease under consideration. The visiting teacher who had aided them in gaining increased knowledge of their subject might with profit then give a short lecture. I believe this reversal of the usual order would increase the value of such courses, and it would be the only kind of education as Mall maintained that really counts, namely self-education.

NOTES ON THE SMALL HOSPITAL AS A CENTER
OF POSTGRADUATE EDUCATION

BY W. EDWARD STOREY, M.D.*

1 A small hospital is easily accessible and familiar to physicians practising in the vicinity. A daily contact with the hospital pathologist and the house officers who have a frequent contact with leaders in large centers gives the practitioner the best practical opportunity to keep informed. In large centers where there is much routine work, research and advanced discussion of problems the practitioner is too often self-conscious, timid, and reluctant to ask questions. This difficulty is more easily overcome in the small hospital where there is more time for explanation and all are familiar to the practitioner.

2 There are those, such as the hospital pathologist and house officers, who are constantly available and who are glad to consult with the practitioner, to suggest accepted measures for diagnosis and treatment and to help him follow up the scientific side of the case.

3 Periodic teaching clinics conducted by leaders from large centers are easily organized and may give the practitioner an extra contact with the very heart of medical progress at no extra cost of time, money, or trouble. Clinics of this character were especially successful at Lewiston, Maine, recently, where they were attended almost unanimously by the staff and by other local physicians who were members of another hospital staff and even by physicians who lived as far as twenty-five to forty miles away (the exact percentage of attendance on these days can be obtained from the registry at the Lewiston hospital). Diagnostic clinics with the patient present were held in the mornings and those present had a first-hand opportunity to see how a difficult diagnosis may be arrived at by narrowing the number of likely possibilities. Ward rounds were made in the afternoon during which all interesting cases on the wards were

reviewed and helpful suggestions made. In the evening some topic of practical as well as scholarly interest was presented in the form of a lecture, often with lantern slides and pathologic specimens, followed by a general discussion in which all were encouraged to enter. The fruits of these clinical days become increasingly apparent in the technique and reasoning of the local practitioners.

4 The presence of a resident pathologist is highly desirable; he makes it possible for the practitioner to avail himself of tissue sections, gross specimen study, and to follow his patient to necropsy with more ease and less expense and embarrassment than would otherwise be possible. The advantage of getting all practitioners to consider as a matter of course the pathologic phase of their cases is obvious.

5 Library facilities, however modest, are a source of information and inspiration to those who otherwise might fail to do any reading or reference work on an interesting case or group of cases. The library at Lewiston was assembled through contributions of books from various staff members. Standard journals in several lines of work were provided through voluntary contributions. The library served a very useful place in the hospital's program of postgraduate education.

6 Through newspaper notices of the hospital activities, members of the community will become increasingly confident in the progressiveness of its local physicians and will be inclined to seek their advice first before going elsewhere.

7 By its welcome to all, the small progressive hospital makes it the accepted thing for a practitioner to manifest his natural interest in scientific medicine without feeling conspicuous or apart in doing so. Indeed, it makes it imperative with the consequent result of a better quality of work.

Storey, W. Edward—For record and address of author see "This Week's Issue," page 22.

INTERNSHIPS IN MASSACHUSETTS HOSPITALS

BY CHARLES H. LAWRENCE, M.D.*

MASSACHUSETTS has three approved medical schools from which there graduate a yearly average of three hundred doctors, practically all of whom seek to fit themselves for the actual practice of medicine by serving as interns in hospitals qualified to furnish them proper experience and instruction in return for the essential service which they render in the conduct of such institutions. There are in this

state thirty-five hospitals which are approved for internships by the Council of Medical Education and Hospitals of the American Medical Association. These offer a total of three hundred and forty-six internships for medical graduates. It is, therefore, possible, at least theoretically, for every graduate of a recognized school in Massachusetts to continue his medical education in an approved hospital within the state.

As a matter of fact, the most recent available

Lawrence, Charles H.—Physician Boston Dispensary. For record and address of author see "This Week's Issue," page 22.

figures show that 237 internships in approved Massachusetts hospitals are occupied by graduates of Massachusetts schools. Of the remainder, twenty-six are held by graduates of schools in other New England states and eighty-two by graduates of schools outside New England. Lacking a statement from each intern, of the reasons for his choice of hospitals no precise conclusions can be drawn from these figures, but they do indicate that practically 80 per cent of the graduates of the schools in Massachusetts find internships more or less satisfactory to them in the approved hospitals in the state, and that competition from other schools, and probably in a few instances personal reasons, compel about 20 per cent to seek internships elsewhere or in a few instances to begin practice immediately. It would be extremely interesting to learn the reasons which determine each intern's selection, and to obtain from him, at the end of his service, an opinion as to whether his choice had been justified by his experience. Such a compilation would furnish material of great value to medical schools, graduates seeking internships, and to trustees of hospitals desirous of increasing and improving their intern staffs.

In default of such information, any consideration of internships must necessarily be one-sided, since the only criteria of their value which can be applied are the rules formulated by the Council, which necessarily define the minimum requirements for approval rather than the imponderable values without which wealth of material and equipment are but sounding brass and tinkling cymbals. Mere numbers of patients in a hospital do not insure that an internship there will best fit a man for practice, nor can it be said that length or type of service are determining qualities, or that adequate laboratory facilities train an intern to appreciate properly the place and value of laboratory aids in the care of the sick. The fundamental quality which makes any internship valuable must be sought in the character and purpose of the hospital's staff and trustees, and consists of an eagerness to equip their juniors with practical training and possibly impractical ideals which shall enable them to maintain and improve the traditions of the profession. Without this spirit, the physical characteristics of a hospital are of little significance.

Since, however, physical characteristics are the only ones which can be accurately measured at present, some help for prospective interns and for the hospitals themselves may be derived from a consideration of this side of the problem. In what type of hospital can a recent graduate in medicine obtain the best training for the kind of work he intends to pursue? How much time can he give to this kind of postgraduate education without encountering sharply diminishing returns? What ratio of

beds to interns will give him the widest possible experience and at the same time afford opportunity and energy for adequate study of the material furnished? Does the "straight" service, limited to a single field, the "rotating" service, which includes successive periods in medicine, surgery, pediatrics, obstetrics, the clinical and x-ray laboratories, or the "mixed" service, in which he may work in more than one field at the same time, offer the best training for him? Tentative answers to these and other related questions can be attempted on the basis of an analysis of the reports on hospitals approved for internships in Massachusetts.

Of the thirty-five approved hospitals in the state, five may be designated general "teaching hospitals" in the literal sense, since their staffs are partially or completely composed of men who hold teaching positions in medical schools, and the patients are used for teaching purposes. Four of these five offer "straight" services varying in length between twelve and twenty-four months. Only one "teaching" hospital offers a rotating service, of twelve months' duration. There are twenty-eight general "non-teaching" hospitals, meaning hospitals in which no formal undergraduate instruction is carried on. In eighteen, the service is the rotating type, in the rest, "mixed." There are two hospitals for patients with chronic disease, in which a little undergraduate teaching is done, both offering rotating services of twelve months' duration. Of the twenty-eight non-teaching general hospitals only three offer services longer than twelve months, and in one the longer term is optional. There would seem to be little danger that the intern services are too long in Massachusetts. The only question to be considered is whether the rotating services are quite long enough.

There has in the past been much argument concerning the relative merits of the various types of internship, one group maintaining that the "straight" service gives a thorough training in one field of practice, and that no man can adequately carry on more than that while another maintains just as stoutly, and probably with equal right, that the rotating service gives a better knowledge of the interrelation of the various fields of medicine and that even to-day the majority of physicians cannot restrict their practice to a single field. It would seem obvious that for the man who intends to restrict his practice to internal medicine or general surgery the straight type of service offers the most complete training, while for the future "general practitioner" the rotating service offers more suitable experience, and for the "regional specialist" either a rotating or a mixed service which embraces at least medicine, surgery and pediatrics furnishes the best antidote for the narrowing influence that such restriction exerts. That a teaching hospital is as a rule more stimulating to the intern than one

in which no formal instruction is attempted may be accepted as generally true, since he is present at many of the teaching exercises, and absorbs much from them. Not all great teachers, however, are collected in the "teaching hospitals." The choice between "straight," "rotating" and "mixed" service would, therefore seem to rest preponderantly upon the type of practice to which the individual intern intends to devote himself. As regards the optimum length of internship, the limiting considerations would seem to be the pressure of necessity and the question of diminishing returns. The first consideration is always a personal one with each intern, the answer to the second depends somewhat upon the type of service, and somewhat upon the variety of material offered by the hospital in question. Obviously a mixed or rotating service might well be longer than the straight type, since even so the time spent in any one field would be much shorter in the former than in the latter. It is the opinion of the Council of the American Medical Association that twelve months is the minimum acceptable term of service, but no maximum term is mentioned in their report. It is conceivable that if twelve months is a satisfactory minimum, a term of more than eighteen months, especially in a straight service, might operate under the law of diminishing returns and might tend to "hospitalize" the intern, to his everlasting detriment as a practitioner.

Perhaps the most important question which can be partially answered in this survey is that concerning the optimum ratio of interns to beds and yearly admissions in any given hospital. These two factors determine the adequacy of material for study, and the amount of time available for other than barest routine duties and thus latter consideration is fully as important as the former in the proper training of an intern. Thorough study of a moderate amount of material is much more important at that stage of medical education than hasty examination of large numbers of patients, since the former develops a habit which lasts through the years that will supply material in increasing amount, while the latter tends to render one incapable of learning by experience.

A study of the ratio of interns to yearly admissions in the approved hospitals in Massachusetts brings to light a marked difference between the "teaching" and the non-teaching groups. In the former there were 354 yearly admissions per intern during the period studied, in the latter 980 yearly admissions per intern. In the two hospitals for patients with chronic disease, the ratio was 489 patients per intern yearly.

Many contradictory conclusions might be drawn from these figures but the true explanation of the differences probably lies in the greater amount of detailed study of each patient required for teaching and research purposes in the

"teaching" institutions. Such work is extremely time consuming, expensive, and yields only a small amount of information immediately applicable to the treatment of the patient upon whom it is carried out. It is, therefore, quite properly not required in non-teaching institutions, with the result that the intern can adequately study and care for a larger number of patients than is possible in a teaching hospital. Therefore, the ratio of three to one between the former and the latter seems proper, when the effort per patient is considered. The only question is whether the interns are overworked in both types of hospitals, and to this question no unbiased answer is available. While they are interns, every man believes they are, after ten years in practice, the same men are sure they were not. No one will deny that it is possible for an ambitious man to do his work adequately and at the same time learn a great deal under present conditions but the question is whether the return is adequate for the energy expended.

A partial answer to this question appears in the analysis of the ratios of interns to beds in the hospitals under consideration. In the entire number the ratio is thirty-four beds per intern, or if the two hospitals for chronic patients are eliminated, twenty-eight beds per intern. In a properly regulated hospital, in which the intern's time is not wasted, this ratio is probably not excessive. Certain conditions not apparent in the figures, however, may make it so. Such conditions are most apt to be encountered in the mixed type of service in which the intern may be constantly interrupted in his work by the conflicting demands of his varied duties and of several members of the visiting staff who may demand his services simultaneously. Only great care and consideration on the part of the staff can prevent such occurrences becoming frequent and harassing and even they cannot defend the intern from the impossible demands which circumstances sometimes create. These potential interruptions constitute a serious objection to any service in which the intern serves in two or more fields simultaneously and should be considered carefully when contemplating this type of internship. A low ratio of beds to interns is the only apparent solution of the problem at present.

Returning to a consideration of the general problem of the ideal number of beds per intern, it appears that the average in the "teaching" group is just under nineteen beds per intern, while in the "non-teaching" hospitals it is just over fifty-one per intern. The maximum ratio in the teaching group is twenty-four to one, the minimum is nine to one. This minimum seems almost too small for proper intern training the object of which according to the Council's report, is "to round out the medical graduate's

training so as to enable him to enter into the general practice of medicine and not to equip him to enter directly on any specialty." One can hardly visualize the demands of nine patients which would be sufficient profitably to occupy along those lines an intern's entire time.

In the non-teaching group the maximum number of beds per intern is 108, an impossibly large number for one man except perhaps in a hospital for patients with chronic disease. There is no adequate reason for this high ratio of beds to interns. The latter usually receive no salaries and their number adds but little to a hospital's expense, and there would seem to be more than enough well-trained graduates to fill the demands for interns in Massachusetts. Service in a hospital with an impossibly high bed-intern ratio offers the intern no adequate return for his services, and tends to develop slipshod methods and the dangerous habit of making "snap" diagnoses. Any hospital with a ratio of over seventy-five beds per intern can hardly expect or intend to make adequate educational return for the services they render. It is perhaps significant that all the hospitals in our list having a bed intern ratio above that figure pay their interns salaries, a custom which obtains in few others in Massachusetts.

At the other end of the scale in the "non-teaching" group stands the bed-intern ratio of seventeen to one. This would seem to be almost too low for the intern's best interests, but if the visiting staff is mindful of its responsibilities, is probably adequate. Certainly that ratio is far more desirable than the maximum cited above.

Thus far the questions to which tentative answers have been suggested have concerned principally time and material in the form of patients available for study under different hospital systems. Equally important, however, is the development of a proper method of study, which only becomes possible if adequate laboratory facilities and systematic instruction in their application and value, are available to the intern. Herein lies the most glaring weakness of the "non-teaching" group of hospitals. Of seventeen hospitals in this group concerning which a definite statement is available, only three have a full time laboratory director, nine have part time directors, in two the direction is described as nominal, in one as "half time," and in two there is no director at all. In several the routine laboratory work is done by technicians, and the interns are required to do only emergency work.

Under any of the systems enumerated except that involving a full time director, the temptation to shirk laboratory work is almost overwhelming. The recent medical graduate is "fed up" on laboratory work and thirsts for patients and contact with them. Certainly there is little excitement to be found in the performance of

most routine laboratory tests, especially when they relate not to one's own patient but to an impersonal "case" that one has never seen and probably never will see. And if the visiting staff apparently succeeds in caring for their patients without recourse to somewhat tedious routine, any but the most conscientious intern soon learns to persuade himself that "a white count probably wouldn't tell us anything" or that there is no necessity for examining the urine. Once established, this habit becomes fixed to the detriment of future patients. The failure of many general practitioners to make the correct diagnosis in many cases lies not in their inability to interpret clinical signs correctly, but in their failure to do a few simple laboratory tests which would serve to direct their attention to possibilities which, without them, do not enter their minds. It is, therefore, of the utmost importance that every intern should acquire the ineradicable habit of checking his subjective impressions by the objective facts available through laboratory methods. This habit will be acquired only under the tutelage of one who has the conviction that laboratory work is essential to proper medical practice, and the time to inoculate lukewarm pupils with that conviction. With rare exceptions, such a combination is encountered only in laboratories to which the director gives his full time and enthusiasm, and every hospital employing interns should have such a director. If the clinical material is sufficient for the intern's needs, the laboratory material should be adequate for a full time director's

An analogous though less pressing situation exists in the departments of radiology in the hospitals concerning which definite information is at hand. In only five are there full time directors. Such instruction as the intern gets he must pick up as best he can, and it usually consists in reading a report of the x-ray findings, rather than study of the films and instruction in interpreting roentgenograms.

Radiology is a specialized procedure and is not essential to the diagnosis as often as are the more humble laboratory tests, but every intern should learn by experience rather than by word of mouth to know the circumstances in which its possibilities justify its expense to the patient or the hospital. He should also learn enough of the difficulties inherent in the interpretation of roentgenograms to give him a proper sense of their value when he is piecing together the evidence concerning an individual patient. To acquire even this minimum learning he must have the opportunity to see the roentgenograms of patients under his care and discuss with a qualified roentgenologist the correlation and discrepancies between the x-ray and clinical evidence.

Manifestly an intern will not get this type of instruction in a hospital in which the roentgenol-

ogist spends only time enough to read the films and dictate his opinions before hurrying to an other institution or back to his own office. While the roentgenological demands of some of the smaller hospitals may not require the entire time of a director of that service, any part time plan should insure that he give more than enough time to meet the minimum diagnostic requirements since only thus can proper instruction of interns be assured.

And finally, if an intern is to receive proper return for his labor the hospital in which he works must in some way provide him access to an adequate reference library. This does not mean an enormous collection of books, but it does mean that a reasonable number of recent standard works be available for reference work, and that the better medical periodicals also be available. In the majority of Massachusetts hospitals outside Greater Boston these conditions are not satisfied. The books on the shelves are outdated and the medical magazines few. Such conditions wean the intern from the valuable habit of keeping in touch with medical literature, so that after graduation his knowledge tends to fall farther and farther behind medical progress.

It is not the purpose of this paper simply to point out the existing defects in the instruction of interns in the hospitals of Massachusetts. Criticism of certain conditions has been offered as affording a basis for planning further improvement, for it must be stated in all fairness that in practically any approved hospital in the state a recent medical graduate can spend a year profitably if he is energetic and interested. What can be done to still further improve the value of the internship to both hospital and intern?

In order to answer this question, further data are necessary, the collection of which involves the cooperation of all who are vitally concerned in medical education: the medical schools supplying interns, the hospitals employing interns,

and last but not least recent interns themselves.

Medical schools should form a committee to advise prospective candidates for internship concerning the hospitals in which they are most certain of getting instruction and experience which will best fit their needs. In order to give such advice, the committee would have to be in possession of facts obtainable only through the cooperation of the hospitals and their recent interns. From the hospitals the committee should obtain information in regard to the various qualifications considered essential for approval by the Council of the American Medical Association. From each intern, on completion of his service, it should obtain opinion of the value of that service embodying specific suggestions for its improvement. Suggestions which the committee considered valuable could be forwarded to the superintendent or trustees of the hospital in question to be acted upon by them. After all, the interests involved are not conflicting but mutual.

There is at present no adequate organization for the solution of these problems and the need for such an organization is perhaps the most important fact which this study has served to emphasize. It also indicates what the composition and functions of such an organization should be. Manifestly, medical schools, hospitals and the Massachusetts Medical Society as well as the interns themselves, are concerned in improving the value of intern services in Massachusetts. Therefore, all of these bodies should participate, by representation in assembling and studying the necessary data which should include not only the usual statistics concerning beds, books, admissions and autopsies but also statements from all interns, on completion of their services, regarding the value of the service from their point of view and embodying suggestions for improvements. Such a study would benefit not only the interns but medical schools, hospitals, and the community as well.

A BAFFLING CASE OF PULMONARY CARCINOMATOSIS*

BY JOSEPH O. EDWARDS, M.D.†

SINCE pulmonary aspergillosis was first described in 1842¹ there has been much discussion as to whether the infection is primary or secondary to other lung conditions such as tuberculosis, abscess, bronchiectasis etc. In the

The Massachusetts Medical Society has provided for the award of a prize of fifty dollars each year to the best written and most comprehensive case report submitted by an intern holding a rotating internship in a Massachusetts Hospital which is approved for intern training by the American Medical Association.

This essay was awarded the prize for 1935. The illustrations were not a part of the material submitted for the award.

*Edwards, Joseph O.—Intern, Springfield Hospital, Springfield, Mass. For recent and aid case of author see "This Week's Issue" page 3.

literature there have been many reports of primary aspergillosis both in man and animal.² It is said to occur in pigeons as a primary pulmonary type. In man, some believe the condition to be primary even in the presence of tuberculosis and such writers reason that since the fungus is so universally present, if the aspergillosis infection be secondary, it should be found more frequently in association with tuberculosis. In the literature, only one instance was found associating aspergillosis with carcinoma of the lung.³ As the authors reporting the case stated that no specific reference in the literature could

be found of aspergillosis infection secondary to pulmonary carcinoma, it therefore seems warranted that the following case should be reported

A report of this case may also serve to direct attention to the importance of a more careful consideration of possible primary conditions when obscured by predominating physical signs, clinical symptoms x-ray and laboratory findings

CASE REPORT

A thirty year old white married American housewife was admitted to Springfield Hospital Oct 28, 1934 with a complaint of cough, dyspnea and weakness over a period of three months. The onset had not been acute and there had been no chills or night sweats

The patient stated that she had not lost weight, but the physician in charge said that the patient's usual weight had been 125 pounds but in September had dropped to 107, a loss of 18 pounds in three months, which loss was attributed to restricted diet, prescribed for relief of vague gastrointestinal symptoms

Her history previous to admission to Springfield Hospital was briefly as follows

April, 1933 Roentgenogram of chest was negative

April, 1934 Complained of gastrointestinal symptoms of obscure nature. Gastrointestinal series interpreted as negative

Aug 30, 1934 Roentgenogram of patient's chest was reported as showing evidence of miliary tuberculosis, while another film taken at this time and interpreted by another radiologist was diagnosed as pulmonary tuberculosis, but not of the miliary type. Von Pirquet test was negative at this time and sputum failed to show acid fast bacilli

Sept 9, 1934 Sputum examination showed tubercle bacilli not found, mold present. penicillium glaucum culture showed mixture of Staphylococcus and a spreader which made definite identification impossible

Sept 24, 1934 Sputum again negative to tuberculosis. Mold present aspergillus

Sept 27 1934 Tuberculosis not found. Mold present but too young to identify. It has the appearance however, of aspergillus. Curschmann's spirals were present. Blood examination at this time: red cells 5,460,000, Hg 75 per cent, white cells 17,000—small mononuclears 16 per cent—large mononuclears 15—transitionals 45—myelocytes 0—polys 75 per cent and eosinophiles 3 per cent with no normoblasts or megaloblasts

Sept. 30, 1934 Roentgenogram of chest reported as follows "From all appearances there seems to be slightly more involvement than there was in plate taken August 30th." A definite opinion was not given, but it was felt that malignancy could not be ruled out and that neither tuberculosis nor fungus infection could be disregarded

Oct. 7, 1934 The patient was becoming steadily worse. Coughing spells were numerous and exhausting

Oct 14, 1934 Examination by a consulting physician showed "nothing but chest signs" no nodules could be palpated in the breasts and examination of heart and abdomen was negative

Oct 23, 1934 Sputum was examined using 40 per cent potassium hydroxide, staining for 30 minutes, and aspergillus was found

Oct 28, 1934 Admitted to the Springfield Hospital, Springfield, Mass. The cough, general condition and particularly the dyspnea had become progressively worse, the relief of which necessitated almost continuous confinement to the oxygen tent

Physical examination revealed a very weak, cyanotic female, poorly nourished and looking very ill. There was great difficulty in raising a frothy white and occasionally blood streaked sputum, containing no yellow particles or pus. The pulse was regular. The heart was normal in size and its sounds normal. There was a slight impairment of resonance over the entire chest, while diminished breath sounds were evident throughout the chest, particularly at the bases which appeared equally involved. Rales were few in number, rather crepitant in quality. Because of the extreme distress from dyspnea on slightest exertion, the patient was too ill to attempt thorough examination. Palpation of the abdomen showed slight distress in the region of the liver and epigastrium but no masses were to be felt. The temperature was 100° F—pulse 110, with respirations 48 to the minute. There were frequent paroxysms of coughing accompanied by labored respirations and extreme dyspnea. Examination of urine showed S P T albumen, 2 to 4 white cells per high power field with occasional epithelial cells. The blood showed Red cells 3,950,000, Hg 70 per cent, W B C 22,400, Polys 81, Lymph 10, Myelos 5 and Eosinophiles 4. Platelets were distributed normally. Smear showed achromia. Sputum negative to aspergillus eight days before death. (Inhalations of ethyl iodide were administered before entry)

Nov 4, 1934 Roentgenogram—firm mottling scattered throughout entire lung fields. Mottling has increased in density since previous pictures

BRONCHOSCOPY

Nov 5, 1934 The mucous membranes throughout the pharynx and hypopharynx are dry, red and inflamed but thickening of these membranes is not apparent. The arytenoids are slightly thickened but show normal motility. The posterior commissure is normal and no granulations are present. The cords appear slightly thickened and quite red but are normally motile and approximate closely. The lateral walls of the larynx are slightly thickened and dark red, due to inflammatory reaction and to cyanosis. The tracheal rings are distinct but do not stand out as white as in the normal and the trachea throughout has a dark, dusky red appearance. The trachea is noticeably deviated, to the right at its middle third, but shows no evidence of compression

The carinal crest is but very little thickened and is quite normal in contour, excepting at its base where it is somewhat broadened. It shows no degree of fixation on inspiration or expiration. The right main bronchus appears dark red and quite cyanosed but its membrane appears but slightly thickened. The branch divisions of the lower lobes, right and left, are not thickened and although deeply red, appear quite normal in contour. Secretion is practically absent although several thick, gelatinous plaques were aspirated. The left main bronchial wall appears to be uniformly smeared with a thin translucent membrane which gave a definitely lighter appearance than that seen in the right bronchus. Because of the patient's serious condition, time was not spent

to examine the upper lobe orifices. As a therapeutic measure 6 cc of Iliodol was installed deeply into the right bronchial tree and 3 cc into the left. Oxygen was administered throughout the examination. Ten per cent cocaine was used in the hypopharynx and 20 per cent applied to carina and secondary bronch divisions. Considering the patient's preoperative condition she reacted well to bronchoscopy.

Six days later the patient died in marked cyanosis with temperature of 97.6—pulse 130—respirations 60 a few hours before death.

The essential pathologic findings were as follows: The lungs appeared solid and shrunken throughout with a uniform surface appearance of mottled gray and white with uniformly distributed fine nodules over the entire lung surface. The lungs were not adherent to the chest wall. There were several ounces of free fluid in the thoracic cavity. The lung

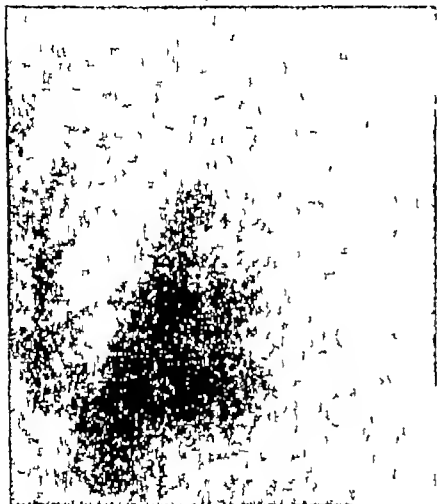

PLATE I. August 30 1934

surface was hard and firm to palpation. Gross section revealed numerous areas varying from 1 cm to 3 cm in diameter of whitish color many of which showed necrotic centers. These areas were uniformly distributed throughout both lungs and in all lobes. The lung tissue seemed almost rubbery to the touch. The bronchi contained a creamy white fluid. There were no ulcerations present. No single large tumor mass was found.

The liver was enlarged its left lobe filling the greater part of the left upper quadrant. There were four well-circumscribed white necrotic masses in the liver occupying a depressed position in the surface of the organ the largest of which was two inches in diameter and about the same in depth. These masses were stellate in appearance at the liver surface. Cultures from these liver masses and from the lungs were negative for fungi but cultured secretions from the bronchi showed pneumococci, staphylococci and streptococci.

The heart was normal in appearance. The intestines, stomach, kidneys and adnexa were normal to gross appearance. One pathologist reported that from the microscopic appearance of the pulmonary

tissue the tumor could well be primary carcinoma of the lung while another thought the sections characterized of metastatic carcinoma. The final diagnosis made by Dr. Frederick D. Jones of the Springfield Hospital was that of primary endobronchial carcinoma of the lung with liver metastasis.

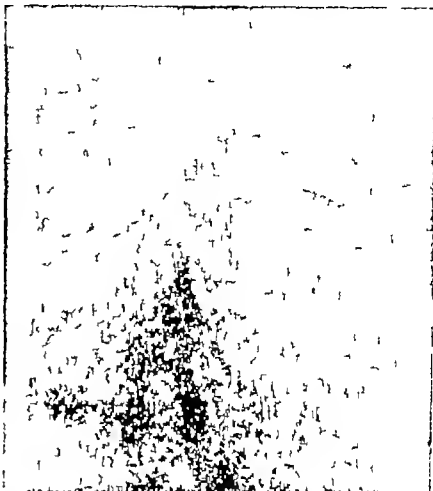

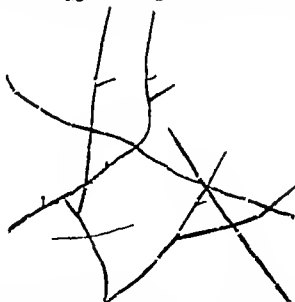

PLATE II. September 30 1934

Hamman states that roentgenologically, pneumomycosis among other things may suggest new growth and that a lesion of the hilum and lower lobes suggests fungi. Aside from the air

(Oil immersion.) Drawing of specimen of aspergillus from smear of sputum of patient. It is identical to the specimen obtained on culture which is more dense and has more branching mycelia with hyphae of short extent which terminate in single rounded ends not unlike conidia.

circumscribed appearance of many bronchiogenic carcinomas of the lung roentgenologically, Rabin and Neuhof say that "the non-circumscribed neoplasms of the smaller bronchi usually present the appearance seen in unresolved pneumonia (at relatively early stages of the growth). Later a lymphangitic carcinosis of both lungs often supervenes. The film then shows the lungs to be

occupied by fine streaks and nodules and the primary growth may not be recognizable. A carcinomatous involvement of the pleura with pleural effusion may occur early in the disease⁵."

Geschickter and Denison in a report of several cases of carcinoma of the lung divide them into two types, (1) the common bronchial or epidermoid carcinomas, or hilar cancer which is composed of epidermoid cells resembling the lining cells of the larger bronchi, and (2) the lobular or pneumonic cancer, which is a diffusely growing adenocarcinoma apparent in the roentgenogram as multiple nodules infiltrating one or

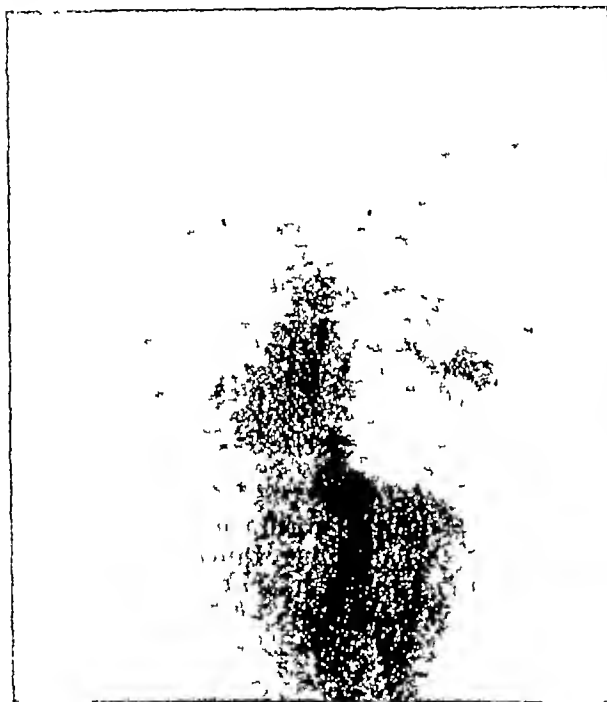

PLATE III November 4 1934

both lungs, usually toward the base⁶. In the latter diffuse type the authors state that adults under forty-five years of age are often afflicted. Microscopically the tumor has an adenomatous structure resembling the terminal ramifications of the bronchioles and sometimes containing a mucoid secretion. These authors believe that the so-called alveolar carcinoma is not an established form, and its existence has never been conclusively demonstrated.

The above-named authors reported several cases of pulmonary carcinoma the youngest being twenty-two years of age and the oldest sixty-five years. A roentgenogram of the twenty-two year old patient showed tumor diffusely infiltrating both lungs after the manner of miliary tuberculosis, with shadows more dense at the bases and in the region of the right lower bronchus. This young patient had had fever, cough, night sweats, and dyspnea of three weeks' duration, and had lost 11 pounds. The clinical impression of this case was miliary tuberculosis. A similar

case has been described by Hamman⁷. In the same article Geschickter and Denison reported another case in which the roentgenogram of an adenocarcinoma produced the picture of a miliary tuberculosis.

In cases of uncomplicated aspergillosis, Emerson states that roentgenograms of the lung show an absence of calcified lymph nodes at the hilum and the apices may be free from disease. At the hilum of one or both lungs a dense shadow radiates in coarse lines usually to one lobe, and radiates peripherally into a diffuse infiltration⁸. He further states that the infection may present a snowflake appearance, such as is seen in pneumoconiosis, the physical signs being those of bronchitis with later signs of infiltration, such as occurs in tuberculosis. The differential diagnosis of aspergillosis, tuberculosis and cancer of the lung may under certain circumstances be exceedingly difficult.

SUMMARY

A case of primary pulmonary carcinoma in association with sputum containing aspergillus is reported. It is believed that the fungus was pathogenic, was secondary to the carcinoma and that its effect on the patient, clinically at least, was deleterious. In differential diagnosis, aspergillosis, pulmonary carcinoma, and tuberculosis were considered, and during a period of several months, all these diagnoses were made with reservations by different physicians who had occasion to examine the patient. The absence of abdominal signs and symptoms, the persistent presence of aspergillus in the sputum and the absence of tubercle bacilli, together with roentgenological and bronchoscopic findings in the chest, suggested that the most reasonable diagnosis was that of pulmonary aspergillosis. Postmortem examination revealed as essential cause of the illness primary endobronchial carcinoma with liver metastases.

The author is indebted to Dr A. D. Rood for the illustrations and the report of the bronchoscopic findings.

THE EFFECT OF ADMINISTRATION OF VITAMIN C ON THE RETICULOCYTES IN CERTAIN INFECTIOUS DISEASES*

A Preliminary Report

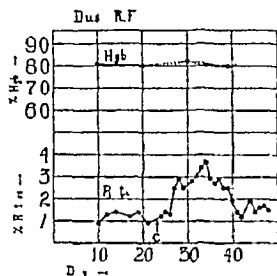

BY JAMES M. FAULKNER, M.D.†

THE effect of administration of large daily doses of vitamin C has been studied in twenty-seven cases of rheumatic fever, eight

cases of bone tuberculosis and two cases of Still's disease. In each of the disease groups were included both active and inactive or recovered cases. None of the cases showed any clinical signs suggestive of scurvy. All the patients had been on a diet generally considered to be adequate in vitamin C. It had contained daily, for all but three of the rheumatic fever patients either 120 cc of orange juice or canned tomato juice or some fresh fruit. In the bone tuberculosis and Still's disease group the diet had included at least one half of an orange daily. The thirty-seven patients varied in age from three to twenty-five years with an average age of 10.6 years. All these patients were given additional vitamin C in the form of 530 cc of orange juice per day by mouth, or in the pure crystalline form in daily doses of 200-800 mg by mouth and in two cases intravenously.

No specific therapeutic effect on the course of

FIG. 1. A typical though small reticulocyte response in rheumatic fever. Beginning at the point marked C, 300 mg per day of ascorbic acid (Celabone-Merck) was given by mouth and continued throughout the rest of the experiment.

the disease was observed during the period of increased vitamin C administration which lasted on the average for four weeks.

In the majority of these cases a response of the reticulocytes followed the large doses of

vitamin C analogous to the reaction which follows the administration of vitamin C to patients with the anemia of scurvy¹. The responses were of small magnitude but the pattern of response, though variable, was orderly. Figure 1 illustrates a typical response of smaller than average magnitude in a case of rheumatic fever. The hemoglobin level was usually above 70 per cent so that the peak of the reticulocyte rise could not be expected to be very great. With lower hemoglobin values there was a slight tendency to higher reticulocyte rises and an increase in the hemoglobin level. Previous administration of large amounts of iron in the form of ferrous sulphate did not prevent the occurrence of the reticulocyte response.

An interesting feature of the reticulocyte response is the fact that it was roughly proportional to the severity of the infection. If the cases are divided into three groups, first, nineteen which showed a rise of 3 per cent or over (average 4.5 per cent), secondly, eleven which showed a rise of between 2 and 3 per cent, and, thirdly, eight which showed no response, it is found that all of those in the first group showed well-marked signs of active infection as measured by body temperature, leucocyte count and corrected sedimentation index of erythrocytes, those in the third group, as a rule, showed little or no signs of infection, and those in the second group showed an intermediate degree of activity. The relationship of the cardinal signs of infection to the reticulocyte response is illustrated in figure 2. The etiology of the infection

was not the controlling factor in conditioning the reticulocyte response.

The failure of large doses of vitamin C to influence the course of rheumatic fever is evidence against the hypothesis of Rinehart² that deficiency of this substance is a specific etiological factor in this disease although more numerous and more prolonged observations are required to reach a final conclusion.

The observation that infections predispose to scurvy is well established and has led to the suggestion that under these conditions the metabolic demands for vitamin C may be much increased^{3,4}. Our results suggest that these demands are not met by diets heretofore considered adequate so that in infectious diseases relative vitamin C deficiency commonly develops and may constitute a secondary complication of some importance.

MEDICAL PROGRESS

PROGRESS IN PEDIATRICS*

BY R. CANNON ELEY, M.D.†

ACUTE ANTERIOR POLIOMYELITIS

AS a result of the clinical evidence which has been presented^{1,2,3} during the past two to three years, the enthusiasm for the administration of convalescent serum as a therapeutic measure in the treatment of the acute or preparalytic stage of anterior poliomyelitis has subsided, and attention is once more being directed toward prevention of the disease.

The development of a vaccine which might be successfully employed as a prophylactic measure in the treatment of poliomyelitis is not new as several attempts have been made in the past^{4,5}. However, with the recent knowledge that favorable results may be obtained with antigens inactivated by germicides in the prevention of

other virus diseases, a new impetus has been given to this phase of study. Maurice Brodie⁶, working with William H. Park, has developed a vaccine which at the present time seems to be efficacious in the prevention of this disease. By employing a vaccine in which the virus has been inactivated by the use of formaldehyde, Brodie has been able to immunize monkeys against poliomyelitis to direct intracerebral inoculation of the virus. Furthermore, the serum obtained from these monkeys possessed neutralizing substances against the virus of poliomyelitis. After having successfully performed these studies in monkeys, the vaccine was injected into members of the research group and these results were in accord with those obtained with the experimental animals.

In 1926 McKimley and Larson⁷, using a vaccine (with sodium ricinoleate as a preservative) that they had prepared from the spinal cords of monkeys killed during the acute phase of the disease injected four monkeys in an effort to

†Eley R. Cannon—Instructor in Pediatrics and Communicable Diseases, Harvard Medical School and School of Public Health. For record and address of author see This Week's Issue, page 33.

establish immunity. Three of these animals failed to develop poliomyelitis when subsequently inoculated with the virus. The fourth monkey developed a slow or delayed form of the disease. All of the control animals died from acute poliomyelitis. The authors concluded that complete immunization had been obtained in three and partial immunization in the fourth monkey. At the same time they pointed out the fact that they had been unable to produce the disease in more than 70 to 75 per cent of the inoculations. However this work suggested the possibility that a suitable vaccine might be prepared as a prophylactic procedure in man. Kolmer² in 1934 successfully immunized a group of *Macacus rhesus* monkeys against acute anterior poliomyelitis by subcutaneous and intracutaneous injections of a vaccine prepared from the spinal cords of infected monkeys and treated with sodium ricinoleate. This preservative, in the amount employed, does not completely kill the virus, yet none of the vaccinated animals showed the slightest evidence of the disease either during or following the process of immunization which consisted of intracutaneous and intradermal injections of small amounts of the vaccine at definite intervals of time. In view of these observations Kolmer suggested that if three subcutaneous injections of this vaccine were given at intervals of five to seven days and in amounts of from 0.05 cc. to 0.1 cc. per kg. of body weight, immunity to acute anterior poliomyelitis might be effectively established in man.

Recently Kolmer² has published the results of this form of prophylaxis in twenty-five patients whose ages ranged from eight months to fifteen years. In each instance the presence of protective antibodies in the blood was determined by serum neutralization tests prior to the injection of the vaccine. In order to determine the effectiveness of the vaccine on both immune and non-immune individuals this group of twenty-five children included fifteen whose blood failed to show any evidence of the presence of antibodies, and ten who did show the presence of antibodies. Each patient received from one to three subcutaneous injections of varying amounts of the vaccine at weekly intervals. None of the children vaccinated showed any evidence of infection, and in only one instance was there a moderately severe local reaction. Febrile reactions which were more commonly encountered after the first injection, were slight and usually subsided after twenty-four hours.

Serum neutralization tests were performed one week after the last injection of the vaccine and 75 per cent, i.e. eleven, of the fifteen children who prior to injection did not show any antibody formation now showed sufficient amounts to neutralize the virus. Similar tests

performed with the blood serum of the ten children who did show the presence of antibodies against poliomyelitis prior to the injection showed an increase in antibody. In view of the rapid antibody formation the suggestion is made that the vaccine cannot only be administered as a means of establishing immunity during normal periods, but that during epidemics it would be particularly valuable as an immunity is rapidly established. In the final conclusions contained in their summary the authors state, "It is believed that the vaccine is now ready for vaccination of human beings and especially children against poliomyelitis and particularly during epidemics."

Although the experimental and clinical evidence as to the value of this vaccine in establishing immunity to acute anterior poliomyelitis as presented by Kolmer and his co-workers is of a most encouraging nature, yet time, further investigations and corroboration of these observations are prerequisites to the acceptance of this procedure. As regrettable incidences^{10, 11} have already occurred in the establishment of immunity against certain diseases we cannot be too cautious—utmost care must be exercised by those who continue this study. Experience has shown that there is an individual susceptibility to vaccines and that many as yet unknown factors may play important roles when a vaccine is injected into a human being. If the virus, even though attenuated, is still present in the vaccine five months after its preparation is it not possible that the preservative may lose some of its attenuating properties, thereby increasing the potency of the virus? (It is recognized that sodium ricinoleate when used as a detoxifying agent with scarlet fever and diphtheria toxin, will under certain conditions lose its detoxifying value.) Theoretically the antibody formation should be sufficient to exert a controlling influence over the presence of the virus in the body but what effect will other diseases have upon this antiviral antibody protection? Furthermore it is believed by many that certain conditions may activate a previously dormant neurotrophic virus. These questions and many others must be satisfactorily answered before the virus of acute anterior poliomyelitis, even though attenuated, should be administered to human beings unreservedly.

CHRONIC PYURIA

A few years ago Helmholtz noted that a specimen of urine obtained from an epileptic patient who was being treated by the ketogenic diet did not show the same tendency for bacterial growth as did specimens obtained from individuals who were receiving a regular diet. As a result of this observation bacteriological studies were instituted which showed that such urines not only inhibited the growth of the colon typhoid

group of organisms but that in many instances they actually possessed bactericidal properties. This effect, however, was less marked for the streptococcus and staphylococcus than for the colon bacillus. In view of these findings it seemed reasonable to apply this form of therapy, i.e., the ketogenic diet, in the treatment of individuals suffering from persistent pyuria, and particularly in that group in which the causative organism was recognized as the colon bacillus. The beneficial effect of this procedure was so marked that Clark¹² reported the successful treatment of two adults and Helmholz¹³ reported similar results in two children who were suffering from an infection superimposed upon congenital anomalies of the urinary tract. During the following two years (1932-1933) the literature contained many case reports supporting the value of this form of therapy.

Further investigations have shown that the bactericidal power of the urine is not due to the presence of either acetone or diacetic acid but that it is directly proportional to the amount of beta-oxylbutyric acid¹⁴ present in the specimen. Fuller¹⁴ has also shown that the effectiveness of this acid depends on the acidity of the urine and that it is only effective at a pH of 5.5 or less.

During the past year the reports in the literature have been so encouraging that it would appear that the ketogenic diet is of unquestionable value not only in the treatment of chronic pyuria in children but also in adults. Clark¹², Gamsborough¹⁷, Helmholz¹⁸ and others have directed attention to its value in the treatment of adults while Rector and Wheeler¹⁹, and Summeifeldt and Brown²⁰ have reported equally as good results in the treatment of children. Rector and Wheeler instituted the ketogenic diet in fourteen patients who had failed to show any improvement when subjected to the usual forms of therapy, and of this group the urine became sterile in twelve cases. In two of the fourteen patients the authors were unable to produce a state of ketosis and it is interesting to note that both of the children showed anatomic deformities of the urinary tract. Summeifeldt and Brown studied forty children with persistent pyuria and reported successful results in those patients in whom no anatomic abnormality was present. This is rather an important point for it would appear that satisfactory treatment does not usually occur if there is some abnormality of the urinary tract. For this reason the authors stress the importance of a thorough examination including pelvesgrams, renal function tests, and in certain instances cystoscopic examinations before the institution of the dietary régime. The prerequisites for successful treatment depend upon (1) the selection of suitable patients, (2) the rapid production of ketosis, (3) a strongly acid urine (pH 5.5 or less) and strict adherence to the diet which, however, does not have to be maintained for a long period of time.

WHOOPING COUGH VACCINE

The recent observations of Leslie and Gardner²¹, and Sauer²² and his associates have not only reawakened interest in the prophylactic vaccination against whooping cough, but have also offered an explanation for the conflicting reports as to the value of vaccines in the treatment of this disease. This form of therapy is not new as it was first employed over twenty years ago²³ and since that time there has developed a rather voluminous amount of literature which is full of conflicting reports as to the value of the procedure in both prevention and treatment of the disease. Not infrequently the same observers have reported both success and failure in the prophylactic use of vaccines prepared in identical manner.

The aforementioned studies have confirmed the earlier observations of Bordet and Sleswyk²⁴, i.e., that recently isolated strains of the *Bacillus Pertussis* differ serologically from old and stock cultures grown without blood in the medium. Furthermore, they have shown that hemolysis is more pronounced in recently isolated strains than in strains under prolonged artificial cultivation and, of probable significance, that the antigenic power of the organism appears to be high on first isolation but fails with prolonged repeated growth on artificial media, unless blood (and preferably human blood) is present in certain proportions. In fact Sauer²² states that the recently isolated strains of Bordet-Gengou bacilli should be grown *only* on Bordet medium made with twenty per cent fresh, defibrinated human blood.

In view of these previously unrecognized facts an explanation for the failure of some vaccines and the success of other vaccines that have been employed in the past is offered. The vaccine employed by Bokay²⁵ was quite successful when used as a prophylactic measure in an institutional outbreak of the disease, but when confirmation of these studies was undertaken on a large scale the results were not so promising. Madsen^{27, 28, 29}, who had the opportunity to study two epidemics of whooping cough in the Faeroe Islands, concluded after the 1923-1924 epidemic that "Vaccination had no effect once the disease had broken out, it should be used, however, to the widest possible extent as soon as the epidemic threatens. No absolutely sure prophylactic effect has been obtained, but the infection is lightened." In the second, or 1929 epidemic, 1832 individuals received the vaccine as soon as the epidemic threatened. The fatality rate was thirty times as great in the unvaccinated as in the vaccinated group of patients. Madsen was of the opinion that the explanation for this marked difference lay in the fact that the vaccine was prepared from fresh, young strains of the organism, and that large doses were given.

In 1933 Sauer²² reported the results of pro

phylactic vaccine therapy in 394 selected non-immune individuals and offered evidence which strongly indicates that pertussis vaccine, when made from recently isolated, strongly hemolytic strains, grown on Bordet medium made with freshly defibrinated human blood, and given in adequate dosage at least four months before exposure, will produce effective immunization against the disease. To quote: "In the course of five years the thirty-one control children in twenty-four of the families contracted unquestionable whooping cough. Twenty-nine of the injected children were exposed throughout the incubation, catarrhal, and paroxysmal stages but none contracted the disease. Not one of 162 injected children accidentally exposed has had a cough that in any way resembled pertussis. Active immunity is completed in four months and lasts for years." In a later publication Sauer²⁰ is careful to point that "no claims are made for it as a therapeutic agent nor when exposure has already occurred or threatens."

In view of this last statement it is of interest to call attention to a new type of pertussis vaccine that has been developed by Krueger²¹ and his associates. This vaccine known as *Heinophilus Pertussis Endoantigen* is a filtrate of the crushed bacterial bodies of the pertussis organism and therefore a more rapid absorption and immunization might be expected by the injection of this bacterial free preparation. The rapid absorption of this vaccine not only offers the possibility of treating an individual who has recently been exposed to the disease, but also the possibility of instituting treatment during the catarrhal period of the infection. Frawley et al.²² have presented clinical evidence which would indicate that the antigen is of both therapeutic and prophylactic value. Among one group of twenty-one children who were treated during the course of the disease 76 per cent had mild attacks, in another group of 165 cases 86 of whom had the antigen within one week after the onset, 59 per cent had mild, 19 per cent moderate, and 12 per cent severe attacks. In a large group of 614 children who were vaccinated as a prophylactic measure 12 per cent of the vaccinated group and 10 per cent of an unvaccinated group developed whooping cough but 62 per cent of the vaccinated group had mild attacks in comparison with 12 per cent of the unvaccinated group who had mild attacks. Minns and Aldrich²³ have recently employed Krueger's endoantigen in the treatment of 122 cases and exposures during an epidemic in Winnetka Illinois and from their observations have concluded "that the majority of children who receive the antigen will have mild attacks of pertussis. Although the prophylactic effect is more uncertain the antigen apparently has the definite effect of modifying and shortening a majority of pertussis infections. This fact is par-

ticularly true when the antigen is given early in the attack or before onset of the cough."

If one were to judge from the clinical data that have been accumulated, it would appear that the employment of pertussis vaccine as a prophylactic measure is probably justified. However when one considers the marked variability in the severity of whooping cough in individual cases the effectiveness of the administration of a vaccine as an active prophylactic measure is still open to question.

PROGRESSIVE PSEUDOHYPERTROPHIC MUSCULAR DYSTROPHY

In view of the number of case reports in the literature concerning beneficial symptomatic treatment a brief review of this condition is of interest.

Although Duchenne²⁴ is usually considered as having published the first description of this disease in 1849, he was actually antedated by Semmilla in 1834 and Costa and Gloga in 1836. During the following twenty years the primary myopathies were gradually differentiated from the atrophies of nervous origin. The former group has been further subdivided according to the anatomic distribution of involvement so that at the present time five types of this disease are recognized.

The etiology continues to be poorly understood, and, as one might expect, numerous factors have at one time or another been considered. Goldstein²⁵ has suggested that it might be the result of some endocrine disorder with particular reference to the pineal body. Barker²⁷ has demonstrated definite physical and metabolic evidences of endocrine dysfunction, Landé²⁸ has reported a case associated with *dystrophus adiposogenitalis*. Janney Goodhart and Isaacson²⁹ have found changes indicative of general endocrinologic disturbances such as dry brittle hair, pigmentation of the skin, acroecic features, trophic changes in the nails and unusual distribution of subcutaneous fat. Kuré and Okumaki³⁰ have concluded that the disease is the result of an alteration in the autonomic innervation of the muscles and on the basis of their experimental work have devised their form of treatment. Syphilis, as well as other diseases of the central nervous system has been found associated with this disease but there is no evidence to support the view that the condition is the result of any of these disturbances. Heredity unquestionably plays an important part and it is not unusual to see two or more members of the same family affected. This is particularly true in regard to brothers. A study of a family in a secluded Swiss village where accurate records for three hundred years were available has shown that the hereditary features according to the mendelian theory are of the recessive mode.

Aring and Cobb⁴¹ have recently published a careful study entitled "Muscular Atrophies and Allied Disorders." In this study efforts have been made to divide the various muscular disturbances into an idiopathic or "Primary" group where the etiology is unknown while those due to known etiological factors are classified as "Secondary." On this basis they have collected three groups of "Primary" atrophies, i.e., sporadic diseases, hereditary myopathies in which the lesions are practically entirely in the muscles themselves, and an hereditary group in which the pathology is largely in the spinal cord. The importance of such a classification and division of the myopathies becomes evident when one realizes that the form of therapy employed in the treatment of those disturbances which are secondary to metabolic dysfunctions are different from those instituted in the group in which the disturbances are secondary to pathology of the nervous system. A careful study of this publication is advocated for those who are interested in this subject.

More recently attention has been directed toward the creatine and glycogen disturbances in these diseases, as abnormalities in the metabolism of both of these substances have been repeatedly demonstrated. McCrudden and Sargent⁴² pointed out the low blood sugar content present in their patient and attempted to explain the muscular weakness by the low glycogen content of the muscles. Milhorat, Techner and Thomas⁴³ have shown that these patients have a creatinuria even on a creatine-free diet and excrete creatine almost quantitatively. This is a complete reversal from that which occurs in the normal individual. Similar observations have been made by Magee⁴⁴ and by Levene and Kristeller⁴⁵.

Treatment in the past has been both discouraging and futile. Recently, however, encouraging reports have appeared in the literature and at the present time two methods of therapy have been offered.

Based on their experimental evidence Kuré and Okinaka⁴⁶ in 1930 suggested that these patients should be treated with pilocarpine and adrenalin. The authors treated twelve patients in this manner and were able to obtain improvement in six, "functionally" complete cure in two, but no improvement in the others which, however, were far advanced cases. Hough⁴⁷ in 1931, treated sixteen patients with this method and obtained improvement in every case although several of them were quite advanced. Of this group eight showed slight improvement, four moderate improvement, and four showed marked improvement, in one case that was comparatively early "a symptomatic and functional recovery" was obtained. Both authors are care-

ful to point out that this form of therapy is *not* a cure, that relief is only temporary, and that the treatments have to be repeated at regular intervals. In a second communication in 1933 Hough⁴⁸ states that the procedure "is of sufficient value to justify its continued use in this disease."

The second therapeutic procedure was offered by Milhorat, Techner and Thomas⁴³ in 1932 and is based on the effect of glycine administration upon creatine metabolism. These authors treated three patients suffering from progressive pseudohypertrophic muscular dystrophy by the oral administration of 5 Gm of glycine daily for eight periods of three months each with an interval of three weeks between each period of treatment. Chemical studies showed that the creatinuria was definitely increased and that after a period of a few weeks this gradually decreased until it had reached its former level, although the glycine had not been discontinued. Clinically there was a slow disappearance of fatigue which was accompanied by increased activity and an improvement in motor acts that were formerly executed in a very poor and awkward manner. Chanutin, Butt, and Royster⁴⁹ treated five patients in this manner with improvement in three, the other two showed improvement at first but soon became worse. Mettel and Slocum⁵⁰ treated three patients with marked improvement in two and slight improvement in the other one. Beneficial therapeutic results have also been reported by Kostakow and Slauck⁵¹. Beard and Tripoli⁵² obtained improvement in their patients by the oral administration of either glycine or glutamic acid and also observed a creatinuria, which after two or three weeks gradually disappeared. Thus, they considered, indicated a retention of muscle creatine in the body. Harris and Brand⁵³ were unable to detect any striking improvement as reported by Thomas, Milhorat and Techner⁴³. In an attempt to evaluate the efficacy of the two procedures, i.e., the use of adrenalin and pilocarpine and the use of glycine or glutamic acid, Voshell⁵⁴ treated fourteen patients and concluded that the patients who received adrenalin and pilocarpine responded more favorably. Cuthbertson and MacLachlan⁵⁵ have recently reported the results of prolonged glycine administration in nine cases of muscular dystrophy. Five of the nine cases were of the pseudohypertrophic type and except for one case there was definite improvement as evidenced by gain in weight, and gain in strength. In view of the consistent chemical abnormalities that have been repeatedly demonstrated by different observers in this type of muscular dystrophy it would appear that the best therapeutic results should be expected from that form of therapy which is directed toward the underlying metabolic disturbance. At the present time the administration of amino acetic acid

offers the patient greater hope than any form of treatment heretofore employed

As the term "Glycine" is gradually replacing the synonym "Glycoecoll" in chemical nomenclature it is advisable to point out that there is now available on the market a toxic substance used by photographers in developing films which is dispensed under the term "Glycin." On account of the similarity of the two names unfortuna te mistakes have been made and unpleasant accidents have occurred. For this reason the Council on Pharmacy and Chemistry of the American Medical Association has adopted the term "Aminonacetic Acid" as a means of protecting the public against accidental poisoning. It is strongly urged that physicians prescribing this substance will conform with the requests of the Council.

FIRE RESPONSIBLE FOR LOSS OF LIFE AND PROPERTY

It has been reported that, since the founding of the Republic, the losses of life and property due to fires have exceeded the losses in all of the wars carried on by the United States.

Every minute, on the average a building fire occurs somewhere in this country and every day about twenty people die because of fire. Burns with out deaths cause a known addition to the losses by fire.

The total economic loss is more than one billion dollars a year. Most of the fires are due to carelessness and are preventable. A film on fire prevention which can be used as an educational measure may be obtained on application to the Aetna Life Insurance Company of Hartford, Connecticut.

TUBERCULOSIS VIEW OF DUBLIN DISPUTED

Controverting Dr. Louis I. Dublin, who in a recent speech predicted complete control and eradication of tuberculosis in a half century the National Tuberculosis Association went on record as stating the disease the principal cause of death between the ages of 15 and 40 and the directors in a resolution called for an increased fight against the plague.

Although the resolution in no way named the insurance statistician it was viewed by many physicians as significant because it so closely followed Dr. Dublin's talk on control of the disease.

The resolution adopted was as follows:

Resolved that in view of the fact that tuberculosis is still the leading cause of death between the ages of 15 and 40 and is also the most important cause because controllable added stress should be laid on the continued importance of a vigorous campaign against tuberculosis.—New York Times June 26

MANY VOLUNTARY HOSPITALS HAVE HAD TO CLOSE

It is reported that, for the six years following 1928, nearly 600 voluntary hospitals in the United States have had to close their doors and at the present time several hundred others are in a precarious condition.

In 1934 these voluntary hospitals admitted nearly five million people. The cause of this situation is the decreasing support which has been supplied by generously disposed persons. Such hospitals have been drawing on invested funds and have been unwilling to continue service to the people up to the limit of their resources.

CASE RECORDS of the MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

FORWARDED BY RICHARD C. CABOT, M.D.

TRACEY B. MALLORY, M.D., *Editor*

CASE 21271

PRESENTATION OF CASE

A sixty-one year old German night watchman entered complaining of hoarseness and general pains of four months' duration.

Approximately two years before admission while in Munich he had a chill. This was followed by an increase in frequency and nocturia which he had had for a few years. A month later, after he had returned to this country, a cystoscopy and an intraurethral operation were performed under spinal anesthesia at a local hospital. No report was given to him but he felt much relieved, although he still had nocturia about two or three times. About a year later, approximately nine months before admission, his frequency increased somewhat and he also had slight incontinence. Five months before admission he had another operation at this same local hospital following which he was started on a series of bladder irrigations. In spite of all treatment frequency returned and one month later he had a third operation which consisted of a transurethral prostatic resection. A note from his local hospital revealed that his first operation consisted of a right vesiculo-ureterotomy for a ureterocele. Phenolsulphonephthalein test at that time showed a 15 per cent excretion from the right kidney and 35 per cent from the left kidney in nine minutes. The appearance time was five minutes on both sides. The second cystoscopy done at that hospital showed a kink in the right ureter. This ureter was dilated and the renal pelvis lavaged with 1 per cent silver nitrate. Pyelograms showed the kidneys normal in size, shape and position. Shortly after this operation he developed hoarseness which did not improve and which he believed had become slightly worse. At the same time he began to have pains in his legs, hips, back and shoulders. These pains were fleeting but very severe and occurred at practically any time although they were brought on very often and made much worse by climbing stairs. He had continued work until about one month before admission at which time he entered a hospital for massage and baking. While in the hospital laryngoscopic examination showed fixation of the left vocal cord due to paralysis of the left recurrent laryngeal nerve.

The patient was born in Germany but had been in the United States for the past forty-three years. He had the ordinary childhood diseases including a questionable attack of rheumatic fever. Very often he had sore throat. Forty years before admission he had a severe attack of gonorrhea and a few years later had a flare-up. For the past thirty years he had rheumatism which affected various joints, particularly the arms, shoulders and back. About fifteen years before entry he had a penile lesion but it disappeared in a few weeks. He had had two others like it since then.

His father died at the age of seventy-two of strangulated hernia. His mother died at seventy-five of cardiac failure. Two brothers died at the ages of thirty-four and fifty-eight of rheumatism. Another brother died at home of tuberculosis at the age of twenty-six. He had one sister seventy years old who was living and well except for rheumatic pains. Another sister died in an asylum.

He had been married for thirty-four years. His wife died four years ago of hypertensive heart disease. She had had one miscarriage, no children.

Physical examination showed a well-developed man lying in bed, not acutely ill. He had an acetone breath and showed evidence of recent loss of weight. There was moderate pallor of the skin. His voice was hoarse and upon expiration was soft and rasping. The heart was moderately enlarged on both sides. There was a soft systolic murmur heard over the precordium and frequent extrasystoles every four to ten beats. The heart sounds were distinct. The blood pressure was 120/83. There was an external non-bleeding hemorrhoid. The right lobe of the prostate was firm and hypertrophied, the left lobe indurated but not clearly nodular. The right knee joint showed slight impairment in extension and was larger than the left. The increased size appeared to be due to hypertrophic changes of the joint bones or cartilage.

The temperature was 97°, the pulse 98. The respirations were 22.

Examination of the urine on admission showed a specific gravity of 1.010, a large trace of albumin and large numbers of white blood cells and clumps of granular casts. The blood showed a red cell count of 3,300,000, with a hemoglobin of 60 per cent. The white cell count was 4,400, with a differential of 52 per cent polymorphonuclears, 45 per cent lymphocytes, one large mononuclear, one eosinophil and one basophil. Examination of the stools was negative. A Hinton test was negative. The nonprotein nitrogen was 46 milligrams per 100 cubic centimeters, the uric acid 3.36 milligrams. A complement fixation test for gonococcus was negative. An electrocardiogram showed auricular fibrillation, rate 150 with ectopic ventricular contractions and

point in the whole story It cannot be laughed off

X-RAY INTERPRETATION

DR. GEORGE W. HOLMES This is the chest film He has a high diaphragm on the left side with gas below it which I would interpret as being intestinal gas The left border of the heart is obscured It is not enlarged to any extent He has a slight increase in the supracardiac shadow This is the ascending and thus the descending aorta It is not possible to measure the accurate diameter of the aorta from the film But I think it is within normal limits The diameter of the aorta varies considerably There is nothing abnormal in the lung fields In view of the story of laryngeal paralysis one might suspect the esophagus There is no obstruction and no indication of tumor

This second film is an oblique view to show more completely the aorta, here the arch, ascending and descending portions are quite distinct, certainly nothing there to suggest aneurysm or any gross dilatation The pelvis shows a small group of calcified shadows in the region of the prostate gland I think that calcification is more likely to occur in an inflammatory process than in malignant disease The bones of the spine and pelvis are normal There is nothing to suggest a bone lesion Here is a group of dense shadows in the soft tissue They may be glands or an old hematoma and are of no particular importance The joint spaces show very little change

In the skull we have a rather prominent grouping of the blood vessel markings but no definite evidence of disease.

DIFFERENTIAL DIAGNOSIS CONTINUED

DR. ALBRIGHT It seems to me fairly clear that, with a big heart, with a nonprotein nitrogen of 46, and with the delayed appearance of the dye he certainly had some renal insufficiency I think the terminal event is renal insufficiency and uremia He had twitching and went out like a person who had uremia The question is what was the cause of the kidney lesion The first thought is some type of kidney associated with Bence-Jones protein The urine examination is perfectly typical of a kidney lesion in myeloma with Bence-Jones protein He had a large trace of albumin, clumps of granular casts and white blood cells What was more important, he did not have any edema, which would be surprising if he had those same urinary findings in ordinary chronic nephritis It is also of some significance that he had a serum protein of 6.6 This is a normal value, the fact that it is not low suggests some factor tending to elevate it such as myeloma We are not told how much there was in his urine

The kidney gets into trouble apparently in Bence-Jones proteinuria due to plugging of the tubules with the Bence-Jones protein

The next question that comes up is the cause of the Bence-Jones proteinuria in this case I think one is apt to believe that it is always due to multiple myeloma and in 99 per cent of the cases it probably is I looked up this question this afternoon It is known to occur with leukemia and Dr. Minot told me he is sure he has seen it in metastatic malignancy I have seen it in one case with proved hyperparathyroidism

In favor of myeloma is this perfectly characteristic onset of bone pain The slightly elevated calcium and slightly elevated phosphorus in the blood are in favor of myeloma You usually think of a myeloma skull as one with a whole lot of sharply defined defects in it, but we have cases that have not shown that I remember a case with uniform decalcification and nothing to suggest localized areas So I see no reason why we cannot make the diagnosis of multiple myeloma with secondary renal involvement There is a second possibility, metastatic malignancy We turn our minds to the prostate He had this trouble starting originally in the prostate with incontinence, then this laryngeal paralysis right after manipulation of the prostate, as though something might have gone from the prostate perhaps into the brain It is hard to believe that he would have got such a localized area with metastases to the brain but it is possible so we have to consider cancer of the prostate It is also true that it is unusual to get metastases to bone without seeing lesions by x-ray Prostatic cancer can do that because of its osteoplastic tendency when it forms bone rather than destroys it and may cause uniform density with no changes in the x-ray We do not have to consider hyperparathyroidism Leukemia is pretty well ruled out The spleen was not enlarged The third possible diagnosis would be chronic nephritis with uremia, on the theory that the Bence-Jones protein had nothing to do with it He had, however, no hypertension and no eye ground changes Amyloid disease, in view of the chronic sepsis and the large amount of albumin in the urine, is a possibility If he had that, he should have had a low serum protein and edema

The final possibility is that all this did start with cystitis and pyelitis and that he did die in uremia as the result of a pyelonephritis I would like to know what the temperature was and if he did die of sepsis I think that is unlikely because the white count was low

My final diagnosis, however, is that he had multiple myeloma with myeloma kidneys and death due to uremia, a chronic infectious arthritis that probably started with a gonococcus urethritis and chronic prostatitis, arteriosclerotic heart disease with chronic fibrillation

CLINICAL DISCUSSION

DR. ARLIE V. BOCK This has been a very illuminating discussion by Dr. Albright from my point of view. When the patient arrived on the ward my impression was that he had malignant disease. There are at least two types of response in people who have malignant disease, one having a quite normal appearance, even though you know certainly that malignancy is present. The second type have a facies that is quite characteristic of malignant disease. This patient fell in the latter group. In looking him over pretty thoroughly we excluded the prostate among other possible causes of malignancy. The suggestion of myeloma occurred to us and the Bence-Jones protein was found by Dr. Jacobson. We were surprised by the relatively huge amount present in the urine. Then we were a bit disappointed in not being able to get any confirmatory evidence of myeloma on the basis of the x-ray findings, all of which seemed to be negative from that point of view. He did have evidence of chronic nephritis. He died in a state of uremia and while we felt that there was little doubt of his having myeloma, we discharged him with a question of myeloma instead of making a positive diagnosis because we know that other cases of malignant disease may have Bence-Jones protein in the urine.

CLINICAL DIAGNOSES

Chronic nephritis
Uremia
Hypertrophic arthritis
Myeloma?

DR. FULLER ALBRIGHT'S DIAGNOSES

Multiple myeloma
Myeloma kidney
Uremia
Infectious arthritis
Chronic prostatitis
Arteriosclerotic heart disease

ANATOMIC DIAGNOSES

Plasma cell myeloma, diffuse.
"Myeloma kidney"
Septicemia, streptococcus non hemolyticus
Hyperplasia of retroperitoneal glands
Hydrothorax, left.
Diverticulosis of the sigmoid and descending colon
Pleuritis, chronic fibrous.
Pericarditis, chronic fibrous, localized

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY The autopsy on this man was at first very disturbing. We could not find anything until we got down to his kidneys, which were somewhat smaller than normal, 225 grams, the normal would be nearly 350 grams. When the capsules were stripped the

surfaces were very pale gray. It was quite obvious that there was something wrong with them.

The remnants of his prostate were somewhat hypertrophied and contained some calcification. The heart was perfectly normal. The coronaries were negative, the aorta negative. There was a little emphysema. Naturally in view of the story of the finding of Bence-Jones protein we examined a number of bones and they all looked perfectly normal. The cortex was not thin, the trabeculae were present in normal numbers. The marrow seemed a little grayer than normal but there were no tumor foci, so that until the microscopic sections came through we really had no idea what the situation was.

This first slide is a total cross section of a vertebra. You can see the layers of cortical bone on either side and between them an approximately normal distribution of marrow cells and fat cells. When we come down with the higher power, however, we find that between the fat cells the vast majority of the cells are of one type, with dark staining, basophilic cytoplasm and a perfectly round eccentric nucleus. They are typical plasma cells and comprise at least two-thirds of all the marrow cells present.

The lymph nodes were at first thought to be normal but more careful examination showed numerous plasma cells scattered through the pulp. The spleen and liver, however, escaped the infiltration.

The kidneys present the typical picture seen in cases of multiple myeloma. The convoluted tubules are free from casts but the straight tubules—both Henle's loops and the collecting tubules—contain very numerous exceptionally dense hyaline casts. The glomeruli and tubules show only slight arteriosclerotic changes. This type of kidney lesion is characteristically limited to the myeloma cases which show Bence-Jones proteinuria.

DR. BERNARD M. JACOBSON There are a number of interesting features of this case. I should like to say in passing that while the patient was alive Dr. Hunter found a few plasma cells in the smear, a finding that is certainly abnormal and which might be interpreted as evidence of plasma cell type myeloma.

The masses described in the x-ray report in the region of the shoulder and on the left side of the pelvis might possibly be amyloid deposits, a condition described in myeloma which we have not seen at this hospital. They unfortunately were not examined at the necropsy.

CASE 21272

PRESENTATION OF CASE

A five and a half year old girl entered through the Emergency Ward complaining of vomiting of two days' duration.

Two days before entry she awoke very early in the morning and began to vomit. She continued to vomit all that day. The vomitus was described by her grandmother as "phlegmy" fluid which became greenish toward the end of the day. The child ate nothing during that day and had no bowel movement. She was unable to keep food or fluids down. That evening her mother gave her some Ex-lax, following which the patient complained of right-sided abdominal pain which she said had been present all that day. A physician found tenderness in the right lower quadrant and advised admission to the hospital. She had had no pain on micturition.

Her mother, father and one brother were living and well. There was no history of diabetes, carcinoma or tuberculosis.

At the age of nine months she had lobar pneumonia followed two weeks later by measles. During the past six months she had had severe sore throat associated with enlarged cervical glands. She had always had a poor appetite and was quite finicky about her food. Her bowel habits were very irregular. She had been given all sorts of laxatives.

Physical examination showed a very sick child whose skin was hot and flushed. There was herpes on the lips. Both tonsils were enlarged, inflamed and contained on their surfaces patches of yellowish exudate. The chest was clear, the heart negative. The abdomen was soft but no peristalsis could be heard. No masses were felt. There was slight costovertebral tenderness but no spasm on the right side. A rectal examination showed no tenderness.

The temperature was 104° , the pulse 130. The respirations were 24.

Examination of the urine showed a very slight trace of albumin and a green to orange test for sugar. The sediment contained a few white blood cells and occasional red blood cells. There were no casts. The stools were negative. Examination of the blood showed a red cell count of 37 000 88 per cent polymorphonuclears.

Her condition remained unchanged on the second day except for a slightly lower temperature and pulse. On the fourth day the patient was more alert but very irritable. She cried out whenever touched. Her abdomen was resistant throughout to deep palpation. Both costovertebral angles were tender but this seemed to be fairly superficial. That evening a fine punctate rash appeared. The throat was not acutely inflamed. The temperature was 104° , the pulse 120, the respiration 25. She still was very irritable and resisted examination. Her abdomen was kept rigid voluntarily but could be softened when desired. She had one bowel movement that evening following an enema. On the fifth day the child's neck became stiff and Kernig's sign was positive. A lumbar puncture showed clear fluid with an initial pressure of 220 milli-

meteers which rose to 350 upon jugular compression and promptly fell following release. There were four cells, all lymphocytes. A Pandy test for globulin was negative. The sugar was slightly increased. An ear consultant found no definite abnormality. Two days later the child appeared in fairly good spirits and showed only slight spasm in the right upper quadrant anteriorly but extreme costovertebral tenderness. Her temperature was 104.4° . Examination of an uncentrifuged specimen of urine showed 4 to 12 white blood cells per high power field and an occasional red blood cell. A centrifuged specimen was loaded with both red blood cells and white blood cells and showed a positive guaiac test. The white blood cell count was 21,000. An intravenous pyelogram showed the kidney outlines on both sides. The right appeared considerably larger than the left, but both were smooth in outline and normal in shape. The dye appeared promptly on both sides. On the right the pelvis was imperfectly filled and there was no filling of the upper major and minor calices. The bladder was not remarkable. On the ninth day operation was performed.

DIFFERENTIAL DIAGNOSIS

DR EDWARD L. YOUNG JR. Any child of this age who starts to vomit is at once under suspicion of beginning one of the exanthemata or one of most any of the acute infections and it is the starting point of so many things in a youngster that it really means very little. The fact that it came on several hours before any abdominal pain is the reverse order in which appendicitis generally appears and is I think, worth paying attention to. Of course, the other side of that picture is the fact that at five and a half appendicitis is often very atypical and, of course, must always be considered.

On examination the only lead we are given is that of probable sepsis somewhere because of temperature and a possible source of sepsis in the tonsils. The white count is very high and the polymorphonuclear percentage likewise. This backs up our feeling that we have got to find the source of infection. The abdominal examination would seem to rule out a focus of trouble there sufficient to cause this temperature. The lack of peristalsis does not fit into the picture as it appears at this stage of the game. The continued tenderness in the costovertebral angles may be of importance but there has to be more to go with it before it will lead us anywhere. Of course, a urinary infection in a child will make them just as sick as this child apparently was. I do not see any record of urinary culture, however, which might have helped. It is not unusual, in fact according to some urologists, it is a very common thing to have the throat the starting point of acute pyelitis or pyelonephritis.

On the fifth day the child showed evidence of meningeal irritation but the lumbar puncture would seem to rule out any definite meningitis. The ear consultant was called in on the basis that at this age the ears are one source of unexplained temperature. He did not help out, however.

The one thing that seems to continue is the costovertebral tenderness, apparently increasing with particular attention directed toward the right side. The urine also seems to point toward trouble in this neighborhood and it seems to me that a perinephric abscess has to be considered a very definite possibility. We know that a certain number of perinephric abscesses start from small cortical abscesses which rupture into the perinephric tissue. In those cases the urine will show the organism on culture and there will be microscopic blood and pus in the sediment. In other cases, probably about half of them, a perinephric abscess is a definite metastatic process in the perinephric tissue itself. The perinephric fat is a definite entity with its own blood supply and early in the process the infection is localized and can cause a great deal of pain. It is an interesting fact coming from some clinics that the delay in diagnosis, apparently unavoidable, is considerable. I believe that at the Mayo Clinic it is reported as over thirty days. The study of the kidneys suggests that there is some trouble in the right side and it seems to me in the face of the evidence we have that an exploratory operation directed toward a perinephric abscess is definitely indicated.

PRE OPERATIVE DIAGNOSIS

Abscess of right kidney

DR. EDWARD L. YOUNG'S DIAGNOSES

Perinephric abscess

Abscess of the kidney

OPERATIVE NOTE

"Oblique incision in right loin. In exposing the kidney it was found that the perirenal fat was edematous and adherent. In freeing the upper pole of the kidney an abscess cavity was broken into with the escape of considerable

thick, odorless pus. The kidney was densely adherent throughout, allowing evidence of long standing infection. The kidney was removed without difficulty. Two wicks were placed one to the site of the upper pole of the kidney and one to the pedicle, and the wound was closed in layers."

FURTHER DISCUSSION

DR. YOUNG: There is very little more to say. The condition is undoubtedly cortical abscesses rupturing into the perinephric tissue. In these border line cases it is always questionable whether to drain the abscess and leave the kidney intact or to do a nephrectomy. We know that in doubtful cases it is probably safer to err on the side of nephrectomy as a secondary operation is more difficult. Here they felt that the only safe thing to do was to remove the kidney.

The prognosis is of course excellent although later in life if this person becomes pregnant she must be under close observation to be sure that her only remaining kidney does not make trouble.

PATHOLOGIC DIAGNOSES

Pyonephritis

(Carbuncle of kidney)

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY: The kidney which was removed at operation turned out to be a typical example of a so-called carbuncle of the kidney. The upper pole was swollen to nearly twice the size of the lower pole by a large number of practically contiguous abscesses, varying from two to ten millimeters in diameter. Some of these abscesses were immediately subcortical and a few of them had obviously ruptured into the perinephric tissues thereby giving rise to the perinephric abscess. Others were immediately beneath the pelvic epithelium and here again a few had broken through and served to account for the pus in the urine. The probable source of this type of infection is hematogenous.

Seven years later the family moved to Arlington. His premedical education was acquired at the Worcester (Mass.) Academy and his medical degree was conferred by Boston University School of Medicine in 1897. Later he studied at the Harvard Medical School.

He was a Fellow of the Massachusetts Medical Society and the American Medical Association. In 1914 he became Superintendent of the Ring Sanatorium and Hospital, and President of the Corporation.

During the war he was Chief of the Neuropsychiatric Service at the Army Hospital at Fort Sheridan. He retired with the rank of Major. He had been Assistant Professor of Neurology at the Boston University School of Medicine for many years. He was prominent in Masonic bodies, and many civic and social organizations.

Dr. Ring is survived by his widow, Dr. Barbara Ring, who is Treasurer of Ring Sanatorium, a son, Hallam T. Ring, business administrator of the Sanatorium, a brother, Harold E. Ring, a sister, Mrs. Willard F. Gay, and a grandson, John Hallam Ring, all of Arlington.

POLLANO—WALTER A. POLLANO, M.D., of 238 Havenshill Street, Lawrence, died from a heart attack, after a brief illness, June 25, 1935. He was born in Sessa Aurunca, Italy, in 1879. His early education was acquired at the University of his native city and at the University of Naples. After coming to America he became a registered pharmacist and later graduated from the Middlesex College of Medicine and Surgery, and served an internship at the Lying In Hospital in New York City.

He was a Fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, Mrs. Dora Pollano, a daughter, a son, four brothers, and a sister.

SWAN—WILLIAM DONALD SWAN, M.D., of 167 Brattle Street, Cambridge, died June 25, 1935, at his summer home in Annisquam.

Dr. Swan was born in Kennebunk, Maine, the son of Joshua and Sarah (Hodges) Swan in 1859. His premedical education was acquired at Harvard College where he received his A.B. with the class of 1881. He graduated from the Harvard Medical School in 1885. He served as intern at the Massachusetts General Hospital and the Boston Lying In Hospital and then pursued postgraduate studies at Vienna. On his return he engaged in practice in Cambridge.

He was a Fellow of the Massachusetts Medical Society and the American Medical Association and had served as medical examiner of the first Middlesex District for over thirty years. He was honorary president of the Cambridge Hospital, having previously served as President and Trustee. He was a member of the Harvard Club, the Union Club of Boston and the Laurentia Club of Canada.

Dr. Swan is survived by a son, William D. Swan

and a daughter, Mrs. J. Frank Brown, and a sister, Mrs. J. Beiram Williams.

WITHEE—FREDERICK ELMARIAN WITHEE, M.D., of 9 Forest Street, Newton Highlands, died June 30, 1935. He was born in Vassalboro, Maine, in 1864, and graduated from the College of Physicians and Surgeons of Baltimore in 1892.

He joined the Massachusetts Medical Society in 1897 and retired in 1931. He was also a Fellow of the American Medical Association. He maintained practice until within a day of his death. He was a member of the Staff of the Newton Hospital for seventeen years, and on his retirement was made an honorary member. He served as physician to Newton schools for twenty-nine years and during the World War served as captain in the Medical Corps at Camp Devens. He was a member of the American Legion.

His widow, Mrs. Addie L. (Brown) Withee, survives him.

OBITUARIES

DR. DUNCAN CAMPBELL SMYTH

Dr. Duncan Campbell Smyth was born on May 8, 1885, at Port Hood, Nova Scotia. He was the son of Christopher Smyth and Ellen Somers and grandson of the Hon. Peter Smyth. He died June 11, 1935.

He received his early education at the Port Hood Academy and later at the University of St. Francis Xavier's College in Antigonish, Nova Scotia. From this college he received the degree of Bachelor of Arts in 1904. Following the footsteps of his brother, the late Dr. P. Somers Smyth, prominent eye specialist of Boston, who died in 1929, he entered the Harvard Medical School and graduated therefrom in 1909. He interned at the Massachusetts Eye and Ear Infirmary subsequently engaging in practice in Boston.

On January 1, 1914, he married Alice G. Rice and by this marriage he leaves two children, a daughter, Pauline, aged seventeen years, and a son, Duncan, aged twenty years.

Dr. John E. Somers, who practiced his profession in North Cambridge for many years, was an uncle of the deceased.

Dr. Smyth was a Senior Surgeon in the Department of Otolaryngology at the Massachusetts Eye and Ear Infirmary. He was a finished operator. He made a distinguished name for himself in bronchoscopy and esophagoscopy. He invented two bronchoscopic instruments and one operation bears his name. His record in removing foreign bodies from the bronchi is exceptionally brilliant. He was distinguished for his good judgment and his dislike of fads and shams. He was one of the first to recognize the value of the formation of the Thoracic Clinic at the Massachusetts General Hospital and was the strongest representative of the Infirmary on this service. His opinions were highly valued by the members of this group. In the American Bronchoscopic Society, of which he was Vice Presi-

On the fifth day the child showed evidence of meningeal irritation but the lumbar puncture would seem to rule out any definite meningitis. The ear consultant was called in on the basis that at this age the ears are one source of unexplained temperature. He did not help out, however.

The one thing that seems to continue is the costovertebral tenderness, apparently increasing with particular attention directed toward the right side. The urine also seems to point toward trouble in this neighborhood and it seems to me that a perinephric abscess has to be considered a very definite possibility. We know that a certain number of perinephric abscesses start from small cortical abscesses which rupture into the perinephric tissue. In those cases the urine will show the organism on culture and there will be microscopic blood and pus in the sediment. In other cases, probably about half of them, a perinephric abscess is a definite metastatic process in the perinephric tissue itself. The perinephric fat is a definite entity with its own blood supply and early in the process the infection is localized and can cause a great deal of pain. It is an interesting fact coming from some clinics that the delay in diagnosis apparently unavoidable is considerable. I believe that at the Mayo Clinic it is reported as over thirty days. A SYMPOSIUM ON MEDICAL EDUCATION IN MASSACHUSETTS

In this issue, for the first time, the Massachusetts Medical Society through its Committee on Medical Education and Hospitals has attempted to draw attention to certain phases of medical education which are of particular local interest.

The manner in which physicians are registered in our Commonwealth can be improved. In order to bring about most wisely a reform of this character it is essential, as a starting point, that doctors be familiar with the history and nature of our present licensure law. The Editor of the *Journal* has described this clearly and succinctly.

Books play an important part in any process of medical education. The article by Dr. Lincoln Davis, President of the Boston Medical Library gives some idea of what a well-run library may accomplish as a center of postgraduate instruction and describes how the Library in Bos-

ton is eager to lend a helping hand to all physicians in the community who are interested in availing themselves of this unique collection.

Hospitals form a necessary link in any chain of medical progress. Dr. J. H. Pratt and Dr. C. H. Lawience have discussed hospitals and their relation to education from different viewpoints, Dr. Pratt pointing out how the community hospital can be made into a vitally important center of postgraduate education, and Dr. Lawience reminding the staff members of hospitals approved for intern training that they are obligated to teach their interns carefully and systematically and, therefore, assume teaching responsibilities as definite as those undertaken by members of the faculty of any medical school.

Finally, the case report by Dr. Joseph C. Edwards illustrates the quality of work that Massachusetts interns are capable of performing. This paper received the prize offered this year by the Massachusetts Medical Society for the best case report written by an intern in a Massachusetts hospital approved for intern training and offering a rotating internship.

The opportunities for postgraduate education in Massachusetts are varied and open to many, and in the future they can be developed to even greater advantage than they have been in the past. One cannot have attended the recent meeting of the Society without realizing how widespread throughout our ranks is the earnest, sincere desire to know more and to do better work. The more intelligently the opportunities at hand are used, the more rapid will be the growth of general medical knowledge.

INFANTILE PARALYSIS CONVALESCENT THERAPEUTIC SERUM

ON page 36 of this issue, Dr. Chadwick sounds a timely word of warning as to the therapeutic value of infantile paralysis convalescent serum. As the next few months will inevitably witness a normal seasonal increase in the incidence of the disease, and may even see the unfolding of an epidemic that no one today can foresee, it is well that the medical profession should realize the limitations of a serum, the use of which is too often based on emotional rather than scientific grounds.

With the attention given to infantile paralysis during and after the 1916 epidemic, it was devoutly to be hoped that some specific therapeutic agent might be found. For some years, the studies carried on in this State under the auspices of the Harvard Infantile Paralysis Commission offered encouragement to the belief that the serum, if used in the preparalytic stages, might be of some therapeutic value in minimizing the subsequent paralysis. Even through the 1931 epidemic individual instances were numerous in which favorable effects followed, and might

therefore be due to the serum. Even these, however, were subject to the criticism provoked by a lack of control cases for it was manifestly impossible to make certain that the treated cases had not been of milder type than those already paralyzed and therefore not treated. Studies in other states, where serum was not so readily available and where more skepticism existed as to its value showed beyond dispute that when the value of serum was measured by comparison with a control group of alternate cases, no scientific evidence could be brought forward to support the belief in its efficacy.

Thus were shattered our hopes that convalescent serum might serve as a specific therapeutic agent. It is safe to say that in its continued use today the physician is merely hoping against fact that his particular case will in some way show some improvement that may be attributed to the serum. In the absence of any other specific therapy, and keeping in mind the popular hysteria with respect to the disease, the use of the serum is not greatly dissimilar to the drowning man's frantic grasp at a passing straw. The most that can be said for the serum is that its use may to a certain degree allay popular panic and give to the victim's parents a measure of comfort in the thought that something tangible is being done. Beyond this it is apparently of little value. It is to be hoped that the medical profession in its proper eagerness to afford to its patients every possible aid to recovery, will not lose sight of the real facts as to the value of convalescent serum.

HONORIS CAUSA

It has been rare indeed in the last decade and a half, to have material of any importance spread upon the pages of the *Journal* without its first coming under the scrutiny of the managing editor. Special occasions, however, justify unusual methods and his associates on the staff of the *Journal* take this means of congratulating Doctor Walter Prentiss Bowers on their own behalf and on that of the Massachusetts Medical Society on the honor which Harvard University has done itself in conferring upon him the degree of Master of Arts, *honoris causa*.

This degree has been conferred upon our friend, not as the editor of the *Journal*, not as a former president of the Massachusetts Medical Society not on account of his arduous labors on the committee investigating the costs of medical care not as a former secretary of the Board of Registration in Medicine, but on account of the years which he has given to his community as a skilled and devoted practitioner of the art of medicine.

THIS WEEK'S ISSUE

CONTAINS articles by the following named authors

BOWERS, WALTER P. M.D. Harvard University Medical School 1879 F.A.C.S. Managing Editor, *New England Journal of Medicine* Member, Massachusetts Board of Registration in Medicine, 1894-1921 His subject is "The Massachusetts Board of Registration in Medicine" Page 1 Address 8 Fenway, Boston, Massachusetts

DAVIS, LINCOLN A.B., M.D. Harvard University Medical School 1898 F.A.C.S. President, Boston Medical Library His subject is "The Value of the Medical Library in Medical Education" Page 5 Address 279 Beacon Street, Boston Massachusetts

PRATT, JOSEPH H. Ph.B., A.M. M.D. Johns Hopkins University School of Medicine 1898 Physician in Chief, New England Medical Center Professor of Clinical Medicine, Tufts College Medical School His subject is "The Community Hospital as a Center of Postgraduate Education" Page 7 Address 270 Commonwealth Avenue, Boston, Massachusetts

STORLEY, W. EDWARD M.D. Emory University School of Medicine Atlanta, Georgia 1930 His subject is "Notes on the Small Hospital as a Center of Postgraduate Education." Page 11 Address Columbus Georgia

LAWRENCE, CHARLES H. A.B. M.D. Harvard University Medical School 1908 Physician, Boston Dispensary Instructor in Medicine, Tufts College Medical School His subject is "Internships in Massachusetts Hospitals" Page 11 Address 520 Commonwealth Avenue, Boston, Massachusetts

EDWARDS, JOSEPH C. A.B. M.D. Harvard University Medical School 1934 Intern, Springfield Hospital Springfield Mass His subject is "A Baffling Case of Pulmonary Carcinomatosis" Page 15 Address Springfield Hospital, Springfield Massachusetts

FAULKNER, JAMES M. A.B., M.D. Harvard University Medical School 1924 Visiting Physician, House of the Good Samaritan. Research Fellow, Thorndike Memorial Laboratory and Junior Visiting Physician, Boston City Hospital Assistant in Medicine, Harvard Medical School His subject is "The Effect of Administration of Vitamin C on the Reticulo-epithelium in Certain Infectious Diseases" Page 19 Address 264 Beacon Street, Boston Massachusetts

MASSACHUSETTS LEGISLATIVE NOTES

House No 2245

Reported on House No 1894

Referred to Ways and Means, House

RESOLVE providing for an investigation and study by the commissioner of public health of the laws relative to public health and to the establishment and administration of a system of health insurance

RESOLVED That the commissioner of public health is hereby authorized and directed to make an investigation and study of so much of the Governor's address (printed as Senate No 1) as relates to a study and revision of the laws relating to public health, and of the subject matter of current house document numbered fourteen hundred, relative to the establishment and administration of a system of health insurance Said commissioner shall report to the general court the results of his investigation and study, and his recommendations, if any, together with drafts of legislation necessary to carry such recommendations into effect, by filing the same with the clerk of the house of representatives on or before the first Wednesday in December of the current year For the purposes of this resolve said commissioner may expend, subject to the approval of the governor and council, such sums, not exceeding, in the aggregate, one thousand dollars, as may hereafter be appropriated therefor

EDITORIAL NOTE

This resolution deals with very important matters relating to the practice of medicine That part which provides for a revision of public health laws should be given careful study by doctors, because there should be no antagonism between practitioners and health authorities

That relating to health insurance is one of the unsolved controversial subjects before the State and Nation in which the medical profession must assist in a solution, fair to all interests if possible, with the fundamental requirement that the people of this country must have adequate medical care

The Commissioner of Public Health has a difficult task before him in this assignment, and will need the assistance of fair minded persons who can submit facts and arguments which will be of assistance in the preparation of his report

House No 1157

The bill designated to permit the licensing of chiropractors was defeated in the House June 26 by a standing vote of ninety two to twenty nine,

after an adverse report by the House Committee on Ways and Means

Representative Olson of Ashland served notice that he would move reconsideration

The attempt to have a reconsideration of the vote the next day was defeated This apparently disposes of the attempt for this year

MISCELLANY

THE NOMINATION OF DR. WILLIAM L HARRIS OF MILFORD

Governor Curley has presented the name of Dr William L Harris of Milford to the Council to fill the position of medical examiner of the sixth Worcester District to succeed Dr George Curley, deceased

ADMISSION TO THE PRENDERGAST PREVENTORIUM

The Prendergast Preventorium conducted by the Boston Tuberculosis Association accepted 110 children for the opening day June 29 Dr Eh Friedman will be medical supervisor for this season

DR RICHARD P STRONG DELIVERS THE MAIBEN LECTURE

Dr Richard P Strong, Professor of Tropical Medicine at Harvard University, delivered the Maiben Lecture in Medicine, at the meeting of the American Association for the Advancement of Science, Minneapolis, June 25, 1935 The subject of the lecture was "The Importance of Ecology in Relation to Disease"

THE APPOINTMENT OF MR FRANK PRESTARA

The Council has endorsed the Governor's nomination of Mr Frank Prestara as a member of the Industrial Accident Board by a vote of five to three Mr Prestara took the oath of office June 26

He succeeds Mr N Fusaro of Worcester

THE ELECTION OF DR E W GOODPASTURE

Dr E W Goodpasture, Professor of Pathology of Vanderbilt University School of Medicine, Nashville, Tennessee, has been elected a Director of the American Society for the Control of Cancer, to fill the vacancy on the Board caused by the death of Dr George H Bigelow

THE APPOINTMENT OF DR R M ASH

Mayor T S Burgin of Quincy, Massachusetts, has appointed Dr Richard M Ash of 66 Greenleaf Street, Health Commissioner of that city

BOSTON UNIVERSITY SCHOOL OF MEDICINE ALUMNI ASSOCIATION

The Boston University School of Medicine Alumni Association recently elected the following officers President Helmuth Ulrich, M D first vice-president,

David L. Belding M.D. second vice-president
C. Wesley Sewall M.D. treasurer Harold W. Rip-
ley M.D. secretary Randolph Jacoby M.D. auditor
Cecil W. Clark M.D. advisory committee Wesley
T. Lee M.D. Harold L. Babcock M.D. Frank Bar-
ton M.D. Milo C. Green M.D. Winfred Grevhol-
ser M.D. Samuel N. Vose M.D.

Boston University Medical School needs a \$500,000 endowment, \$200,000 of which would be used to on large its buildings and equipment, and the remainder for a fund to carry on its work. Dr. Alexander S. Begg, dean of the school, said at the annual reunion of the alumni association.

He suggested that the alumni appoint a fund-raising committee.

The school which was established in 1874 with fifty-eight students has reached a point where it is now teaching in excess of 250 students and has had 1700 graduates. Boston University Medical School was the first degree-granting institution in New England to offer women an opportunity to study medicine.

There were about 500 men and women doctors present. Dr. Harold L. Babcock, 10, retiring president of the alumni, presided and Dr. Edward S. Calderwood was toastmaster.

Four old grads rose and bowed when they were called upon. They were Drs. John P. Sutherland and George Perry, '79; George Hunt '84 and John B. Rice '86. Dr. Perry Wilder represented the class of '25. Members of the graduating class of the school of medicine attended. Dr. Daniel L. Marsh and Charles L. Sullivan, Jr. of Jamaica Plain, Mass., president of the 1935 senior class were guests of honor.

THE 121ST ANNUAL REPORT OF THE TRUSTEES OF THE MASSACHUSETTS GENERAL HOSPITAL

The 121st Annual Report of the Trustees of the Massachusetts General Hospital is a testimonial to the intellectual vigor as well as to the physical health of this institution. The principal points enumerated in the Report may be placed in three groups—Scientific, Economic and Physical.

The outstanding achievement of the year 1934 was the establishment of a psychiatric service under the direction of Dr. Stanley Cobb. This service which was made possible by a grant from the Rockefeller Foundation has at its disposal twelve beds on the third floor of the Baker Memorial. On the same floor are the beds of Dr. Ayer's Neurological Service and Dr. W. J. Mixer's neurosurgical assignment, thus concentrating on one floor all patients with diseases of the nervous system. As the Report points out the significance of this development lies in the close affiliation thus brought about between a psychiatric unit and the life of the General Hospital.

In the Out Patient Department, special clinics

have been formed for the study of osteomyelitis and of headaches of obscure etiology. In the laboratories intensive study is being carried on as to the nature of renal calculi. This work links up closely with the studies which have been made with such important results on the various aspects of hyperparathyroidism: studies in pernicious anemia in endocrinology and in the field of the sympathetic nervous system. A Wolf Schindler gastroscope was purchased in April 1933. Its value has been demonstrated in the differentiation of gastritis and gastric ulcer. Over 200 examinations have been made.

This list does not by any means include all of the investigations being carried on in the various departments of the hospital but it gives one an idea of the scope of the researches under way.

In the field of economic development we find listed an investigation of the financial status of outpatients. During the period from January 1 to May 30, 1934, all outpatients who had been admitted two or more years previously were interviewed as to their financial condition. Seven thousand five hundred and twelve patients were investigated and of this number only forty-eight were found to be ineligible for hospital treatment.

The Trustees have gone on record as favoring a plan of Group Insurance but they are awaiting the cooperation of the other hospitals in the Greater Boston group.

An eight-hour day for nurses has been instituted; data are being collected as to the reactions of patients, nurses and staff to this innovation.

As to changes in the physical aspect of the hospital it is to be noted that the land on the corner of North Grove and Fruit Streets formerly owned by the city has been purchased by the hospital. Some of the buildings thereon are being remodeled to serve as dormitories for male employees. A great need exists for housing facilities for graduate nurses, male nurses and resident doctors. Seventy-one physicians live in the hospital; the facilities of the hospital for supplying rooms to the resident staff are severely taxed.

More beds in the Baker Memorial have been made available for patients for the demand for beds has steadily risen. Two hundred and twenty-six of the possible 300 beds are now in commission.

The hospital has sustained great losses in the death of Dr. George Bigelow and of Mr. Robert Homans and Mrs. Nathaniel Thayer. Mr. Homans and Mrs. Thayer had served for many years on the Board of Trustees their services to the hospital were outstanding.

The Staff has lost through resignations the services of Dr. Tracy Putnam, Dr. Philip Wilson and Dr. Frederick Lord. The first two go to other fields of activity and, as the report suggests, they will add their contribution to that of the large number of Massachusetts General Hospital graduates who in every field of medicine and in many places are putting into daily practice the lessons and the ideals taught them by the Massachusetts General Hospital.

Seven years later the family moved to Arlington. His premedical education was acquired at the Worcester (Mass.) Academy and his medical degree was conferred by Boston University School of Medicine in 1897. Later he studied at the Harvard Medical School.

He was a Fellow of the Massachusetts Medical Society and the American Medical Association. In 1914 he became Superintendent of the Ring Sanatorium and Hospital, and President of the Corporation.

During the war he was Chief of the Neuropsychiatric Service at the Army Hospital at Fort Sheridan. He retired with the rank of Major. He had been Assistant Professor of Neurology at the Boston University School of Medicine for many years. He was prominent in Masonic bodies, and many civic and social organizations.

Dr. Ring is survived by his widow, Dr. Barbara Ring, who is Treasurer of Ring Sanatorium; a son, Hallam T. Ring, business administrator of the Sanatorium; a brother, Harold E. Ring, a sister, Mrs. Willard F. Gay, and a grandson, John Hallam Ring, all of Arlington.

POLLANO—WALTER A. POLLANO, M.D., of 238 Hav-
erhill Street, Lawrence, died from a heart attack,
after a brief illness, June 25, 1935. He was born in
Sessa Aurunca, Italy, in 1879. His early education
was acquired at the University of his native city and
at the University of Naples. After coming to Amer-
ica he became a registered pharmacist and later
graduated from the Middlesex College of Medicine
and Surgery, and served an internship at the Lying
In Hospital in New York City.

He was a Fellow of the Massachusetts Medical
Society and the American Medical Association.

He is survived by his widow, Mrs. Dora Poliano,
a daughter, a son, four brothers, and a sister.

SWAN—WILLIAM DONNISON SWAN, M.D., of 167
Biattle Street, Cambridge, died June 25, 1935, at his
summer home in Annisquam.

Dr. Swan was born in Kennebunk, Maine, the son
of Joshua and Sarah (Hodges) Swan in 1859. His
premedical education was acquired at Harvard Col-
lege where he received his A.B. with the class of
1881. He graduated from the Harvard Medical
School in 1885. He served as intern at the Massa-
chusetts General Hospital and the Boston Lying In
Hospital and then pursued postgraduate studies at
Vienna. On his return he engaged in practice in
Cambridge.

He was a Fellow of the Massachusetts Medical
Society and the American Medical Association and
had served as medical examiner of the first Middle-
sex District for over thirty years. He was honorary
president of the Cambridge Hospital, having previ-
ously served as President and Trustee. He was a
member of the Harvard Club, the Union Club of Bos-
ton and the Laurentia Club of Canada.

Dr. Swan is survived by a son, William D. Swan,

a daughter, Mrs. J. Frank Brown, and a sister,
Mrs. J. Bertram Williams.

WITHEE—FREDERICK ELMARIAN WITHEE, M.D., of
9 Forest Street, Newton Highlands, died June 30,
1935. He was born in Vassalboro, Maine, in 1864,
and graduated from the College of Physicians and
Surgeons of Baltimore in 1892.

He joined the Massachusetts Medical Society in
1897 and retired in 1931. He was also a Fellow of
the American Medical Association. He maintained
practice until within a day of his death. He was
a member of the Staff of the Newton Hospital for
seventeen years, and on his retirement was made an
honorary member. He served as physician to New-
ton schools for twenty-nine years and during the
World War served as captain in the Medical Corps
at Camp Devens. He was a member of the American
Legion.

His widow, Mrs. Addie L. (Brown) Withee, sur-
vives him.

OBITUARIES

DR. DUNCAN CAMPBELL SMYTH

Dr. Duncan Campbell Smyth was born on May 8,
1885, at Port Hood, Nova Scotia. He was the son of
Christopher Smyth and Ellen Somers and grandson
of the Hon. Peter Smyth. He died June 11, 1935.

He received his early education at the Port Hood
Academy and later at the University of St. Francis
Xavier's College in Antigonish, Nova Scotia. From
this college he received the degree of Bachelor of
Arts in 1904. Following the footsteps of his brother,
the late Dr. P. Somers Smyth, prominent eye special-
ist of Boston, who died in 1929, he entered the Har-
vard Medical School and graduated therefrom in
1909. He interned at the Massachusetts Eye and
Ear Infirmary subsequently engaging in practice in
Boston.

On January 1, 1914, he married Alice G. Rice and
by this marriage he leaves two children, a daughter,
Panline, aged seventeen years, and a son, Duncan,
aged twenty years.

Dr. John E. Somers, who practiced his profession
in North Cambridge for many years, was an uncle
of the deceased.

Dr. Smyth was a Senior Surgeon in the Depart-
ment of Otolaryngology, at the Massachusetts Eye
and Ear Infirmary. He was a finished operator. He
made a distinguished name for himself in bronchos-
copy and esophagoscopy. He invented two broncho-
scopic instruments and one operation bears his name.
His record in removing foreign bodies from the
bronchi is exceptionally brilliant. He was distin-
guished for his good judgment and his dislike of
fads and shams. He was one of the first to recog-
nize the value of the formation of the Thoracic
Clinic at the Massachusetts General Hospital and
was the strongest representative of the Infirmary
on this service. His opinions were highly valued by
the members of this group. In the American
Bronchoscopic Society, of which he was Vice Presi-

dent a year or two ago his opinion was equally valued

Dr Smyth was not given to ready speaking. He usually spoke last, and had the gift of hitting the nail on the head. He had a dry wit which brightened any discussion. When necessary he could hit hard. In the Wednesday Clinical Meetings every one felt that the meeting would be a success if he were there and generally he was. He made the hospital his first interest. He did not wait until his time of service came around to appear. Nearly every morning he would show up ready to tease somebody and to help everybody. He was a bit old-fashioned in some ways especially in his loyalty and respect for his superiors. He played a good game of cards. He was a splendid companion and thoroughly a man's man.

Dr Smyth was at the height of his powers at the time of his death. He was next in line for senior positions in medical societies.

A little over a year ago he had warning that he was to share the fate of his brother who died of cerebral hemorrhage five years ago. He had a slight hemorrhage and on June 11 a fatal one.

A few years ago Dr Smyth bought for summer use a house at Marshfield, Mass. which Daniel Webster built for one of his sons and in which at various times Webster himself had lived. Dr Smyth had long been an admirer of Webster and he began to collect Webster items. In the Webster room of Dr Smyth's house a number of valuable Websterian relics were found and transferred to the town authorities. In his pursuit of this material he made a regular and systematic round of the second-hand book shops. Dr Smyth was interested in civic affairs and was a member of the Board of Trade of Marshfield.

He was a lover of birds and dogs. He took great interest in the many birds about his Marshfield home. Working his black and white setter Beverly gave him great relaxation from his medical work. When she was ready to give birth to her first litter of puppies a month or so ago her wolves caused him more concern almost than his hospital duties.

He was a member of the American Laryngological Association, the American Otological Society, the American Rhinological, Laryngological and Otological Society, the American Academy of Ophthalmology and Otolaryngology and the Massachusetts Medical Society. For many years he was instructor in Laryngology at the Harvard Medical School.

He was a member of the Harvard Club of Boston and until recently a member of the Boston Art Club.

H P M

DR. WILLIAM HERMAN
1891-1935

The sudden death of Dr. William Herman on January 25, 1935 brings a poignant realization of the unique position which he had come to occupy in this

community. He was born in 1891 in Nashville, Tennessee and graduated from Yale University in 1912. He then entered business for three years but found that it offered no adequate expression for the humane and esthetic aspirations which made up so large a share of his life. He hesitated for a time between the study of architecture and that of medicine but finally chose the latter and entered the Harvard Medical School in 1916. The extraordinary gift for forming friendships which was his most outstanding trait began at once to make itself felt, among his fellow students, the members of the faculty and diverse artistic and social circles of the city. Professionally it soon became evident that the psychological and sociological aspects of medicine were far more to his taste than the physiological ones. On graduation he completed a medical internship at the Massachusetts General Hospital, then a psychiatric internship at the Phipps Clinic in Baltimore, became attached to the Boston Psychopathic Hospital and worked for a year in Amsterdam under Professor Bronner and Professor Kappers on a problem in neuroanatomy.

As his psychiatric training progressed it became more and more obvious that he must inevitably ally himself with the analytic school of psychology. His unequalled gift of intuition combined with an uncompromising candor and faculty for self-criticism made no other course possible. His proposal to practice psychoanalysis engendered considerable criticism and even ridicule but he calmly held to his plans and convictions without a trace of the truculent attitude which too often mars the discussion between schools of psychology. He received analytical training from Dr. van der Hoop of Amsterdam, Dr. Jung of Zürich, Dr. Franz Alexander and finally Dr. Hans Sachs.

From the first his psychiatric practice was an unqualified success. His gift for obtaining confidence, his keen insight into the depths of complicated situations and his faculty of summing up problems in a vivid and convincing form contained a large creative element which entirely transcended the mere application of technique. He inspired trust and affection in his patients rather than dependence. Perhaps his most spectacular professional success was obtained in the treatment of a group of patients with convulsions which he was preparing to report after several years' observation. He played a large part in the reorganization of the Boston Psychoanalytic Society and it is largely to his wise counsel and breadth of view that the society owes its reputation for liberalism combined with high professional standards which makes it respected throughout the country. He was associated with Dr. Stanley Cobb's department since 1926 and gave every year an elective seminar in psychiatry which has deeply affected the outlook of many students. Plans were maturing to allot him a much larger share of the teaching.

Dr. Herman married Susan Evans Hale of Windsor, Vermont in 1925 and a daughter and a son were born to them.

engorged and pulsating jugular vein a paradoxical pulse and a moderately enlarged heart which was fibrillating. The pleura was markedly thickened, as was the pericardium. At operation an area of pericardium which was partially calcified was removed, but postoperative improvement was slow, so that in 1933 Doctor Churchill again operated and removed a larger amount of calcified pericardium without any further help. A liver biopsy showed slight fibrosis and an omentopexy was done. At the present time he is improving on a restricted salt and fluid intake.

There have been three fatal cases. Two had severe active tubercular pericarditis and died very soon after operation. The other fatal case showed extensive cirrhosis in a fifty-two year old person. Two other patients were slightly benefited and lived about a year after operation.

In summary, Doctor White said that the first symptom is usually dyspnea, abdominal ascites, or both. There is no palpitation. The two most important physical signs are an enlarged liver and engorged jugular veins. There is frequently no pulsation at the right border of the heart by fluoroscope. Many cases have thickened pleura and increased hilus markings. The electrocardiogram usually shows a low voltage with inverted or flattened T waves. The serum protein is frequently low and the liver function is usually normal.

Doctor Churchill spoke briefly of the surgical aspects of Pick's disease. He pointed out that a very sick patient can stand a severe operation if it will relieve him of an overwhelming burden. The patients operated on for Pick's disease frequently are in better condition at the end of the operation than they were at the beginning. If the patient has acute tuberculous pericarditis, he will die as the heart is small and feeble and the tamponade cannot be relieved. Therefore, these latter cases should be avoided surgically.

An excellent motion picture showed the details of the operation. Ether is used for the anesthetic, and the oxygen tent is employed routinely postoperatively. The anesthetic is administered intratracheally to maintain a positive pressure in case the pleural cavities are accidentally opened. There is some danger of opening the heart. The wound is closed tightly with silk sutures.

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING MONDAY, JULY 8, 1935

Wednesday, July 10—

112 M Clinico-Pathological Conference Children's Hospital

Thursday, July 11—

*12 M Clinico-Pathological Conference Massachusetts General Hospital

Saturday, July 13—

*10-12 Staff rounds at the Peter Bent Brigham Hospital. Open to practicing physicians

*Open to the medical profession

†Open to Fellows of the Massachusetts Medical Society

August 29 - September 5—Latin American Congress of Physical Therapy, X-Ray and Radium. For information address Dr. Madge C. L. McGuinness, 1211 Madison Avenue, New York City

October 7-10—American Public Health Association will meet in Milwaukee, Wisconsin. For information address the American Public Health Association, 50 West 50th Street, New York City

October 21 - November 2—1935 Graduate Fortnight of the New York Academy of Medicine. See page 898, issue of May 9

October 28 - November 1—The Twenty-Fifth Clinical Congress of the American College of Surgeons. See page 1065, issue of May 30

BOOK REVIEW

The Newcastle Upon Tyne School of Medicine, 1834-1934. G. Grey Turner, assisted by W. D. Arnison. Andrew Reid & Co., Ltd., Strawberry House, Newcastle upon Tyne, 1934. xii + 221 pages

The history of a medical school is always of interest to the medical profession. This book, written by a well known British surgeon, who has many friends in this country, is an attractive account of the Newcastle School, which recently celebrated its one hundredth anniversary. The book is well illustrated and attractively published.

The New England Journal of Medicine

VOLUME 213

JULY 11, 1935

NUMBER 2

NEW ENGLAND BRANCH, AMERICAN UROLOGICAL ASSOCIATION

HEMORRHAGIC CYSTITIS AND TUBERCULOSIS OF THE PROSTATE*

Case Report

BY O. DRAPER, HELPS, MD†

A man of forty-eight, a wire worker, entered the hospital complaining of hematuria which had existed since the day previous.

Family and past history were essentially negative.

Five months ago he noticed some pain along the urethra, a frequency and discomfort when voiding particularly in the erect position.

His blood pressure was 130/100. Heart normal. Blood picture normal. Bleeding and clotting time normal. Prostate not enlarged. Bleeding was persistent and excessive. He was cystoscoped with unsatisfactory results on account of the free bleeding. He was drained by catheter and there was no let up in his bleeding.

On admission red count was 4,300,000, white count was 15,000. Hemoglobin 70 per cent.

The man was operated upon with the expectation of finding a tumor of the bladder. The operation was done under spinal anesthesia. The bladder was full of clots, no tumor, calculi or areas of definite ulceration were found. The bladder wall seemed to ooze blood from nearly every portion, especially where touched by sponge or instrument. The blood was closed around a large Freyer tube.

At the time of operation his red count was 2,380,000, white count was 10,750 and hemoglobin 50 per cent.

Postoperative diagnosis was hemorrhagic cystitis. His after-treatment consisted of intravenous saline glucose and a transfusion together with a nutritive diet. His convalescence was slow but gradual.

On his discharge the red count was 5,700,000 and hemoglobin 70 per cent.

In the London *Lancet*, Fullerton, in review of 605 cases of hematuria, found the bladder as the source in 470 and of these cystitis and tumor were the most common causes. Bladder injuries and calculi were next in importance.

Podvinec and Pollak in a German periodical mention a vesical purpura as the source of bleeding and Liechtenstein in another article from German literature mentions varicosity as a cause.

The other case is that of a man fifty-eight who entered the hospital on account of a pain in his

back and difficulty in locomotion. He was admitted to the Medical Service.

He was examined carefully. There was noted a slight irregularity in the prostate, a nodule in the left lobe. There were no urinary symptoms. No residual. Cystoscopy was negative and the stains and urologic examination of bladder and both kidney urines were negative.

The spine showed a destructive lesion involving the upper half of second lumbar. Impression was that of tumor, probably malignant.

The diagnosis was probable malignancy of prostate.

This man was operated upon for confirmation of diagnosis.

Suprapubic cystotomy was done under ether anesthesia. A portion of the left lobe of the prostate was removed and examined by our pathologist. Dr. Raymond Goodale by frozen section and no malignancy was found. The wound was closed with drain age. The recovery was uneventful.

On staining and further examination of the portion of prostate removed our pathologist reported the finding of tuberculosis. The slides were reviewed and confirmed by Dr. Shields Warren and others of a Cancer Clinic which met at our hospital at that time.

We feel that this case may be another one of tuberculosis of the prostate gland.

Before leaving the hospital an Albee fusion was done to immobilize the diseased vertebrae.

There are comparatively few cases which are considered definitely as tuberculous lesion of the prostate. Usually a primary focus is located in some part of the body. We found no primary focus in this case.

Patch and Foulds in the *British Journal of Urology* in 1931, reported tuberculosis of the prostate in the absence of tuberculosis elsewhere in the genito-urinary tract as extremely rare.

Lowley and Duff in *Annals of Surgery* in 1930, considered tuberculosis of the prostate as usually secondary.

Barney in 1923 reported a case of tuberculosis of the prostate. The total number of such cases is not large.

Both the patients here reported have obtained a satisfactory restoration to their usual health. The tuberculous prostate case is working and it is a year since his operation. The hemorrhagic cystitis case is working and it is about six months since his operation.

VESICOINTESTINAL FISTULA*

BY HAROLD L. LELAND, M.D.†

THE chief interest in the case I have to present tonight lies in the chronological development of events, and I will endeavor to present it from that viewpoint

On August 4 of last summer, Mrs. A. was admitted to the Ward Genito-Urinary Service of the Lowell General Hospital. Her chief complaint was dysuria and great frequency, of three months' duration, with hematuria for the past three days. The only fact of interest in her past history was her story of so called "bilious attacks" with "much gas", beginning four years ago and recurring at intervals to date, until overshadowed by the urinary symptoms. These attacks were accompanied by slight nausea but never by vomiting. She was constipated and had required a laxative for several years.

Physical examination on admission showed a small emaciated woman, appearing much older than her fifty-one years. The only abnormality to be found was a slight tenderness in the left iliac region, no masses could be palpated.

The laboratory reported a normal blood count, a blood urea of 20 mgm., and an alkaline urine of a very foul odor, having a specific gravity of 1.022, a trace of albumen, and a very heavy sediment filled with pus and some blood.

Cystoscopic examination on the day of admission revealed a bladder with a very offensive urine, so turbid that repeated washing would not permit identification of any landmarks. There was a large, gray, ovoid shadow lying in the base of the bladder, coinciding with the x-ray picture.

A suprapubic cystotomy was performed under novocain infiltration anesthesia. The stone was removed and the bladder closed with a double layer of sutures, being drained with an indwelling urethral catheter.

Her postoperative recovery was excellent. Her temperature never rose above 99°F. She had no discomfort, although her urine remained very foul.

Her wound appeared to be healing by first intention until the ninth day, when it suddenly broke open and discharged a large amount of semi-formed feces and urine.

My immediate thought was that, in closing the bladder under the somewhat restricted field of local anesthesia a stitch had caught a coil of gut and had finally sloughed through into the bladder. I labored under this disquieting illusion for a week, when the intern came to me and said "Doctor, I have just talked with Mrs. A's husband. He tells me that she was passing fecal matter through her urethra for a month before she entered the hospital, but was too embarrassed to tell us about it."

My morale immediately rose 100 per cent.

In addition he said "Here are two stones which she passed last month." One, measuring about two cm. in length contained as a nucleus a small piece of wood, resembling a piece of broken toothpick, the other, a small piece of string.

I accused Mrs. A. of inserting the toothpick into her urethra. This she indignantly, and I think truthfully, denied. We then theorized that the toothpick had entered the bladder from the intestine, causing the fistulous tract.

Her further convalescence was uneventful but slow.

Cystoscopy on the twenty-first postoperative day was unsuccessful inasmuch as the bladder could not be cleared of its fecal content. She refused a gastrointestinal x-ray examination and was discharged on the twenty-fourth postoperative day with the suprapubic sinus well healed, but the bladder still contaminated with feces.

SECOND ADMISSION

Mrs. A. returned September 1 as an outpatient. Cystoscopic examination was again unsatisfactory because of the fecal content of the bladder. A cystogram at this time showed a practically normal bladder contour.

THIRD ADMISSION

On September 15, Mrs. A. again returned as an outpatient.

This time cystoscopy showed a marked improvement. The mucosa revealed a chronic cystitis with a small area low down on the posterior wall which was depressed, irregular and seemed to be the site of the fistula. It did not appear malignant. Attempts to pass catheters and filiforms into this tract were unsuccessful. Both ureters showed a cloudy urinary efflux. They were catheterized in spite of the infected condition of the bladder. Specimens from both kidneys showed pus, bacteria, and a positive culture for colon bacillus. The phthalein test was normal.

Bilateral pyelograms with sodium iodide 125 per cent showed very slight changes which we interpret as being due to infection.

FOURTH ADMISSION

October 4, two months after her original entry, Mrs. A. was again admitted to the hospital. This time she complained primarily of obstinate constipation, with colicky abdominal pains, distention and vomiting. This condition had been developing gradually during the past month.

Physical examination showed a horseshoe-shaped abdominal distention, suggestive of a distended colon from obstruction in the sigmoid. No masses could be felt.

She was relieved by repeated high enemata and pitressin.

During this stay in the hospital a quart of dilute methylene blue was given as a high rectal injection. Her bladder was then viewed through the cystoscope for three quarters of an hour without any color being seen. A bladder injection of methylene blue appeared in the feces the next day.

At this time we felt that she was suffering from a partial intestinal obstruction. We were undecided as to whether this obstruction was caused by a new growth, or by adhesions about the fistulous tract, which apparently was high in the colon, the semi-formed feces excluding the small gut.

She again refused a gastrointestinal x-ray examination, signed a release and left the hospital against advice on the fifth day.

FIFTH ADMISSION

December 3, four months from the date of her first admission, Mrs. A. again entered the hospital. This time she was admitted to the General Surgical

*Read at the meeting of the New England Branch of the American Urological Association, Boston, February 14, 1935.

†Leland, Harold L.—Assistant Professor Genito-Urinary Surgery, Boston University School of Medicine. For record and address of author see This Week's Issue, page 75.

Ward Service with a recurrence of her intestinal obstruction.

Physically she had lost some weight and her general condition was not nearly so good.

The urine still contained a small amount of focal matter.

Cystoscopic examination again failed to permit the introduction of a catheter or siliiform into the fistulous tract. There was nothing in the bladder suggesting malignancy.

A gastrointestinal x-ray now accepted for the first time, showed a filling defect in the sigmoid which could not be filled by a barium enema.

On the tenth day an exploratory operation was attempted under spinal anesthesia with the hope of doing a colectomy.

The abdominal cavity contained a small amount of serous fluid. In the pelvis was a hard mass the size of one's fist. The transverse colon dropped down and was adherent in this mass. The sigmoid and a coil of small gut were likewise involved. The bladder was adherent low down on its posterior wall to the transverse colon.

The bladder was easily separated. A small adhesion no larger than a lead pencil contained the communicating tract with the transverse colon. This was severed and the bladder and colon closed in double layers.

Attempts were then made to bring the sigmoid up for a colectomy. This was impossible because of the adhesions and the great fragility of the tissues which tore and spilled feces into the abdominal cavity.

Finally the peritoneum was brought down to the sigmoid low in the pelvis. The abdominal wall was partially closed with profuse drainage.

The patient did not rally. She died the next day undoubtedly of surgical shock.

Autopsy could not be obtained but a pathological examination of tissue removed from the sigmoid at operation showed a frankly malignant adenocarcinoma grade II.

To summarize We had a simple vesical calculus with an incomplete and therefore misleading history, a fistulous tract between the transverse colon and bladder with subsequent intestinal obstruction from an adenocarcinoma of the sigmoid.

The unsettled question is the relation of the toothpick in the first calculus to the conditions found. Did it cause the fistula, or was degeneration of the carcinoma the cause of the false passage, with the toothpick a mere incident thereto?

DISCUSSION

Dr. F. H. COLBY I enjoyed Dr. Leland's case very much indeed and congratulate him on his presentation. These cases of fistula formation between the bowel and bladder are sometimes extremely difficult to diagnose when the patient is first seen. It is usually a question as to whether the cause of the fistula is in the first place an inflammatory disease affecting usually the sigmoid diverticulitis or whether it is carcinoma. These two conditions account for practically all fistulae except the occasional congenital one between bladder and bowel. While I was at the Brigham Hospital there were two of these cases of fistulous formation between the bladder and the bowel. One patient complained of pneumaturia and the diagnosis was easy of course. The other patient had a persistent cystitis much as in Dr. Leland's case. This patient was gone over very care-

fully both on the general surgical and on the urological services being on the urological service first. Cultures of the urine from kidneys and bladder and complete urological examination resulted in the diagnosis of chronic pyelitis for some time. Then the patient was given a barium enema and one of the nurses reported that barium had appeared in the urine. It is unusual to be able to find the fistula between the bowel and bladder diagnosed at cystoscopic examination unless the fistula is large. It is not frequently made in this manner following a barium enema the barium appearing in the urine.

Carcinoma and diverticulitis apparently cause fistula formation in about the same number of incidences. Both of these patients had diverticulitis.

Divergence of the fecal stream by either a preliminary colectomy or cecostomy and following that, a repair of the damaged bowel either by resection or by a plastic operation are usually the procedures that are followed and likely to be most successful in one of these patients the diseased mass could be removed by a plastic operation on the bowel and a Heineke-Mikulicz procedure done to restore the normal lumen of the bowel. In the other patient, following the colectomy and prolonged drainage of the bowel resection was successfully performed the fistula closed and the bowel eventually closed by a subsequent operation.

These cases are always interesting and should be always borne in mind by us as urologists where a persistent cystitis without any evident cause is present.

Dr. EDWARD J. O'BRIEN There is a very close relation frequency of urination and these diverticula especially when they become inflamed. I have seen several cases in the past four or five years where all the symptoms were those of the urinary bladder when the actual pathology was in the lower sigmoid or rectum. One individual about four years ago first came to me with some frequency of urination. I cystoscoped him but could not find a thing except four or five leucocytes per high power field in the urine. From time to time he complained of pain extending down the left cord into the scrotum. I had him x-rayed and the K. U. B. plates were absolutely negative. Bismuth enema was then done and a diagnosis of diverticulitis of the sigmoid was made. The man went along for about a year and a half without much trouble except for an occasional attack of pain and soreness along the cord extending into the left testicle. Two years ago last January he began to pass some gas through his urethra and that was followed by feces. I sent him to the hospital cystoscoped him and found that he had an opening in the upper left side of the fundus of his bladder. On opening the abdomen there was a large inflamed mass that filled almost the entire pelvis. It was deemed inadvisable to do much exploration in this region so I did a cecostomy thus diverting the fecal stream. This was kept open for about three months with the large bowel irrigated daily with salt solution. The urine became clear and apparently the inflammation of the diverticula subsided. I then closed this cecostomy and the man has been very well since. The urine is clear and is negative except for an occasional leucocyte.

I also saw a case which was sent to me for obstruction of the prostate. There was no residual urine. I cystoscoped him and his bladder looked quite normal. A few weeks later he passed considerable blood by rectum. He was explored and found to have a massive carcinoma of the rectosigmoid.

I mention these facts to show that where we see a lot of patients with frequency and bladder findings are negative we ought to be suspicious of some disease in the sigmoid or the pelvis.

Dr E G CRABTREE I want to call attention to the possibility of demonstrating the sinus if you take an oblique cystogram. Most often these are connected with the rectum in the region of the sigmoid, either carcinomatous or inflammatory in origin, and in the right oblique view, when a dense solution is used, you nearly always see the sinus.

Dr. CLYDE L. DEMING There are no real papers on this subject and I am delighted that Dr Leland presented this subject. The last paper on this subject was written by Hume about thirty years ago. With the advances of our diagnostic procedures it seems to me it would be well for the urologists to bring this subject up to date, because cer-

tainly a great deal has happened in the last thirty years in regard to this subject.

Dr LELAND These things usually run in threes. I had my second case last month. This patient had an admission diagnosis of indirect inguinal hernia, with a large mass low down in the abdomen. He, also, passed fecal material by urethra. He was in *extremis* at the time and no operative investigation could be made. At autopsy he showed a large diverticulum of the sigmoid which had, apparently, eroded through and had communicated with the bladder so that communication between the bladder and intestinal tract is more common than the textbooks would show.

A CASE OF CONGENITAL HYPERTROPHY OF THE VERUMONTANUM*

BY ROBERT R. BALDRIDGE, M D †

CONGENITAL hypertrophy of the verumontanum as a cause of urinary obstruction was first described by Bugbee and Wollstein in 1923¹. The patient was a child three and one half years old. In 1924 the same authors² reported eight cases of posterior urethral obstruction from 4903 autopsy records of the Babies' Hospital in New York City. Seven of these eight cases were demonstrated to have been due to hypertrophy of the verumontanum. They were all under one and one half years of age.

In 1927 Robinson³ described the case of a male, seventeen years of age who was brought to the hospital in uremic coma and who died shortly after admission. Autopsy showed posterior urethral obstruction due to an hypertrophied verumontanum.

Dodson and Lorraine⁴, in 1931, reported another case in a 19 year old male, in whom the verumontanum produced almost complete obstruction of the posterior urethra. Appropriate treatment produced marked improvement. I have been unable to find reports of any other cases in the American or British Journals.

In 1934 Lowsley and Kirwin published a paper entitled "A Clinical and Pathological Study of Congenital Obstruction of the Urethra"⁵. They confined their discussion entirely to valves of the posterior urethra, and did not mention hypertrophy of the verumontanum as a cause of obstruction. Their bibliography is extensive, and includes the work of Bugbee and Wollstein, and of Dodson and Lorraine.

Bugbee and Wollstein and Robinson, studied the pathology of congenital hypertrophy of the verumontanum. In all cases examined the structure was identical with the normal, except for hypertrophy.

The symptoms and pathological findings in

these cases are those of posterior urethral obstruction from any cause.

Symptoms developed early or late, depending on the degree of obstruction and on the degree of compensatory hypertrophy of the musculature above the point of obstruction.

Pathological findings, clinically or at autopsy, are essentially the same in the babies reported by Bugbee and Wollstein, and in the older patients of Robinson, and of Dodson and Lorraine. There is dilatation of the posterior urethra and bladder, and extensive bilateral hydro-ureter and hydronephrosis. The ureteral valves are incompetent.

Symptoms depend, naturally, on the stage of the disease, and on the presence or absence of infection. Those depending on the mechanics of the condition are difficulty in urination, dribbling, frequency, dysuria, but most important of all, intermittent lower abdominal distention and paradoxical incontinence.

The secondary group of symptoms, due to kidney failure, are those of uremia from any cause.

I wish to report the case of an eleven year old boy who was admitted to the Rhode Island Hospital on December 4, 1932. His chief complaints were hematuria and pain over the lower abdomen and also in both lumbar regions. Until two years before admission and, except for measles, chickenpox and whooping cough, his past history had been that of a healthy boy.

Two years before admission the patient first noticed that in the morning his lower abdomen appeared to be distended. This distention disappeared after voiding.

About one year before admission he ran and fell, fell down, on a sled. There was blood in the urine for twenty-four hours. He was seen by a physician, but no treatment was given. From the time of this accident until admission the patient developed progressive symptoms of difficulty in starting the urinary stream, perhaps followed in a few minutes by extreme urgency and incontinence. At times he was totally unable to void. He also noticed an intermittent enlargement of the lower abdomen, with pain in the bladder and in both flanks. The tumor, and likewise the pain would disappear if he

*Read at the meeting of the New England Branch of the American Urological Association, Boston, February 14, 1935.

†Baldrige, Robert R.—Assistant Surgeon in Urology, Chapin Hospital, Providence. For record and address of author see "This Week's Issue," page 75.

were able to void. On these occasions he passed an unusually large amount of urine. Paradoxical incontinence was a feature of the history and bed wetting became a frequent occurrence. During this period the patient often stayed at home from school because of abdominal distention and pain. His appetite was poor.

Several hours before admission he had been wrestling with another boy who threw him and fell on top of him. There was immediate severe pain in the lower abdomen and in both kidney regions. Shortly afterward he passed bloody urine and was brought to the hospital.

Physical examination showed a well-developed and nourished boy lying flat in bed and in no severe distress. Pulse was 100 beats per minute, respirations 24, temperature 98.6 F and blood pressure 110 systolic and 70 diastolic.

Examination was essentially normal except for the abdomen which showed extreme tenderness and muscle spasm in the region of the bladder and of both kidneys. There was a midline abdominal tumor which extended from the symphysis pubis to above the umbilicus.

A soft rubber catheter (F 16) was passed without difficulty and the distended bladder gradually decompressed. The urine was grossly bloody for two weeks. There was a large trace of albumin but no pus or casts. Culture was sterile.

Cystoscopy done on the second day after admission was not very satisfactory. The cystoscope (F 18) met no resistance. The bladder wall lay in great folds which obscured vision and when fully distended was so large that the cystoscopic lens would not focus. We have had the same difficulty in vision when attempting to see objects on the other side of a large dark room by the light of a match.

In spite of the extreme degree of pathology demonstrated by cystoscopy and the intravenous urograms which were subsequently made it is remarkable that on the fourth of December two days after admission examination of our patient's blood gave the following results:

Blood urea nitrogen—17 mgm per 100 cc of blood
creatinine—1.4
Red blood count—5,000,000 cells per cu mm
Hemoglobin—80%
White blood count—9,240 cells per cu mm
Differential count
Polymorphonuclears 65%
Lymphocytes 29%
Transitionals 6%

One week after admission an intravenous renal function test (phenolsulphonethylphthalein) showed the following:

Output of dye 1st half hour—	0%
“ 2nd “ —	20%
“ 3rd “ —	15%
“ 4th “ —	5%
Total output in two hours	40%

Two weeks after admission during which time the patient had been on permanent catheter drainage and his urine had become clear of blood a second cystoscopy was done. The bladder wall was very thin and not trabeculated. It was generally congested. No diverticula, tumors or foreign bodies were seen. Both ureteral orifices were large and gaping. The bladder neck and prostatic urethra were dilated. The verumontanum was enormously enlarged filling the entire nodulated portion of the posterior urethra. It protruded into the bladder neck and could be pushed from side to side. There were no demonstrable valves. The tumor mass did not

bleed easily. It was destroyed as completely as possible by electrocoagulation and the patient continued on permanent catheter drainage.

During the next two weeks the catheter was removed several times and much to our dismay the patient was unable to void. In the meantime he had developed a rise of temperature and a severe urothrits. Four weeks after admission therefore we performed a suprapubic cystotomy for more safe and adequate drainage. We found the bladder wall to be unusually thin, the bladder capacity very great and to our satisfaction no evidence of the tumor we had fulgurated or any other urethral obstruction. We interpret the patient's inability to void as having been due to bladder atony and urethral infection.

After several weeks of suprapubic drainage the sinus was allowed to heal and the patient was discharged voiding normally except for very slight incontinence with a staphylococcus infection of his urine.

He has been seen repeatedly during the last two years and many intravenous urograms have been made. As you see from the reproductions there has been only a slow progress in the regaining of muscle tone of ureters and kidney pelvis.

December, 1933 Before treatment. Ureters difficult to visualize. Very large.

Nevertheless the last group of x-rays taken two years after original treatment (retrograde pyelograms) demonstrate that although the kidneys and ureters have a capacity of fifteen cubic centimeters on each side the emptying time is normal.

Renal function (Intravenous phenolsulphonethylphthalein) done December 15, 1934, two years after treatment and repeated for verification gives the following:

Appearance time of dye (in bladder)—	
3 minutes	
Output 1st half hour—	38%
2nd “ —	33%
3rd “ —	11%
4th “ —	4%

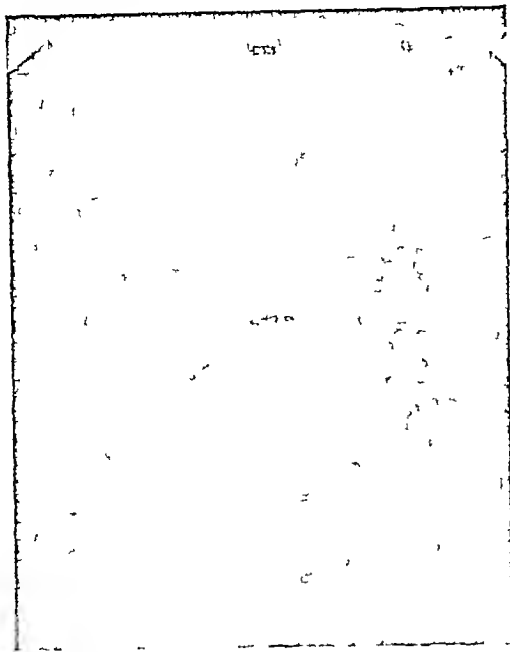

Total output in two hours 86%

Blood urea nitrogen (December 15, 1934)
13 mgm per 100 cc blood

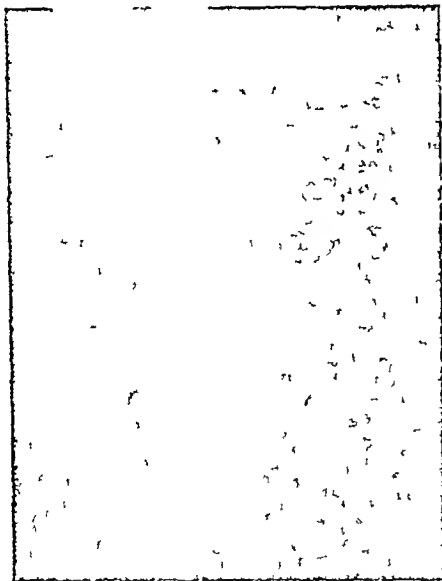

Urine cultures (December 15, 1934)

Right kidney—sterile

Left kidney—staphylococcus albus

December—1932 Before treatment Bladder at body of 4th lumbar vertebra

June—1933 Note size of left ureter and large bladder capacity

Urine examination (December 15, 1934)

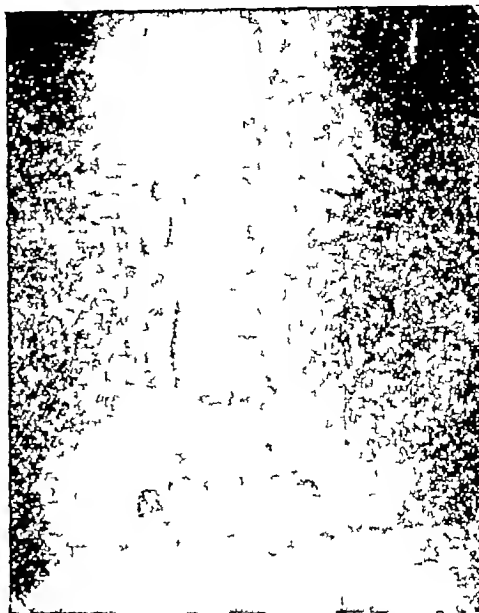

Albumin—slight trace

Specific gravity—1016

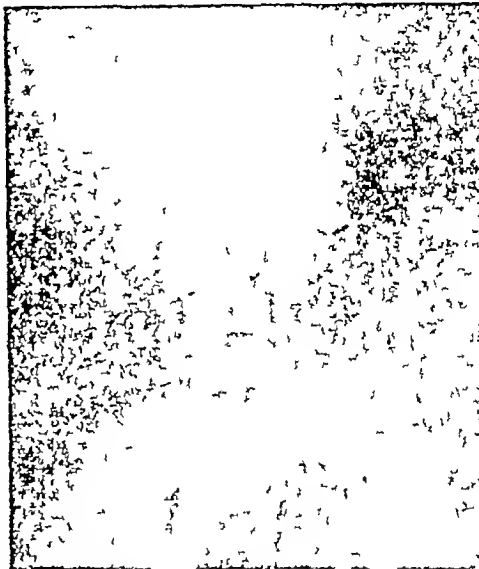

Sugar—none

Microscopic—20 to 40 pus cells, with clumping, per high power field

At the present time the patient is in excellent general health, and his infection is rapidly clearing up. There is no residual urine. Neither are there any symptoms referable to the genito-urinary system except a slight tendency toward incontinence in cold weather.

June—1934 1½ years after treatment

December—1934 2 years after treatment

DISCUSSION

DR F H COLBY This is a very interesting case. Would the ketogenic diet be worth a trial?

DR CLYDE L DEMING I should like to ask what the pathology of the verumontanum was?

DR ERIC STONE I was fortunate enough to see this picture. The tissue was destroyed by fuiguration and it was impossible to get microscopical pic

tures of the specimen. The appearance however of the tissue was in no way remarkable. It looked like a normal verumontanum except that it was out of all proportion to the usual structure. The mucous membranes were normal in appearance over it and its general contour was what one would expect of the usual. The only abnormal feature was the tremendous enlargement of the tissue.

HYDRONEPHROSIS—REPORT OF A CASE*

BY EARL S. MERRILL, M.D.†

URETERAL structure is commonly bilateral and there is no very constant relation between the attacks of pain, the degree of hydronephrosis and the ability of the kidney to function as measured by phthalein excretion.

The following case report shows some interesting variations and illustrates the occasional necessity of ureteral dilatation before operation is attempted.

Present Illness. The patient, a man thirty-eight years of age, first consulted me September 30, 1933. He complained of repeated attacks of pain in the right kidney region. The pain radiated through to the front but not down along the ureter.

These attacks, some mild and some severe, had been recurring with gradually increasing frequency for about fifteen years. They were accompanied at times by nausea and vomiting. There had been no symptoms of urinary infection.

During the preceding year he had several times had a little pain in the left flank. This pain was intermittent, sharp but not severe and did not radiate.

Past History. Outside of the usual childhood diseases his health had been good.

Physical examination was essentially negative except that he was rather pale and thin.

Cystoscopic examination showed a normal bladder mucous membrane.

The ureteral orifices were normal and the ureters were catheterized easily. Sterile specimens of urine were normal on culture and routine examination.

The pyelogram of the right kidney showed very markedly dilated kidney pelvis and calyces.

On the left the injection was not very satisfactory but the kidney appeared to be essentially normal.

A phthalein test was done. The appearance time, following intravenous injection, was two minutes on the left. No phthalein appeared from the right. The left kidney secreted 15 per cent in one half hour.

Because of the low function test he was advised to have the left ureter dilated. A definite hang was found with a No. 10 bulb at about the junction of the upper and middle thirds of the ureter.

The ureter was dilated to a No. 10 Fr. four times before a No. 12 Fr. bulb could be passed. On November 8, 1933, about a month after dilatations were begun the phthalein test was repeated. The left kidney secreted 20 per cent and the right kidney secreted 0.5 per cent in one half hour. Dilatations were continued and after six more treatments a No. 13 Fr. bulb was passed with some difficulty. On Feb-

Dr. BALDRIDGE. I believe that Dr. Colby's suggestion regarding the ketogenic diet is a good one although atypical infections do not respond to this form of treatment so frequently as do the bacillary types. I have nothing further to add to Dr. Stone's discussion.

So far as I have been able to find this is the eleventh reported case of congenital hypertrophy of the verumontanum in the English literature.

runy 9, 1934, another phthalein test was done. The left kidney secreted 30 per cent in one half hour and the right kidney secreted just a trace. The patient at this time stated that he was feeling very much better although he had had several attacks of pain in the right kidney. He also reported that he had gained seven pounds in weight.

I continued dilating the ureter with a No. 13 bulb at about two week intervals.

April 17, 1934, six and one half months after beginning the dilatations, the phthalein test was repeated again. The left kidney secreted 35 per cent in one half hour and the right kidney just a trace.

May 19, 1934, the right kidney was removed. The patient stood the operation very well and convalescence was uneventful.

Since operation the left ureter has been dilated at intervals of about once every two months. The patient has gained about ten pounds in weight.

DISCUSSION

Dr. E. G. CRABTREE. I have nothing in particular to say in discussion of Dr. Merrill's paper except to emphasize the fact that one cannot estimate what reserve the kidney has until it is put to the test. This patient of Dr. Merrill shows return to function that is perfectly surprising.

Perhaps this meeting would be a proper place to put on record a similar story concerning a patient who has been under observation for a long period of time.

As resident at the Massachusetts General Hospital I operated on this woman for two large stones in a hydronephrotic kidney which showed wide dilatation of the pelvis, thinning of the cortex and no function with phenolphthalein. Apparently the stones were the cause of the hydronephrosis. They were easily removed and the kidney was allowed to remain.

Then came the Great War at which time many physicians and surgeons were doing urology often with little time spent on complete study. The surgeon who saw this patient with a cortical infection, due to staphylococcus affecting her remaining kidney, asked her if the opposite kidney had been removed at my operation. When she replied that it had not been removed, he proceeded to do a nephrectomy on the previously normal kidney. After operation there were two or three years of very stormy renal difficulties. Eventually she returned to good health, married and has had three pregnancies, typhoid fever and pneumonia and was still living and seen at the Boston Lying In Hospital last year.

Dr. CLYDE L. DEMING. Dr. Merrill's case is an extremely interesting one. I am going to report briefly a case of a young woman with one child who came to us with extreme pain on one side due to a large hydronephrosis with very little function. On the other side we found an uninfected hypoplastic kidney with only a trace of phthalein function so

*Read at the meeting of the New England Branch of the American Urological Association, Boston, February 14, 1935.

†Merrill, Earl S.—Chief Surgeon, Urological Service, Eastern Maine General Hospital. For record and address of author see "This Week's Issue," page 75.

that we found ourselves practically in the same position as did Dr Merrill. One kidney seemed to do most of the work and the opposite one was practically of no value. Necessity demanded that we save that kidney in some way. We were obliged to do a plastic on the hydronephrosis and she recovered very well. Others of you have probably

had somewhat similar experiences, finding yourself in the position that we have, when necessity demands that we save the kidney one way or another. I am sure we are forced to use conservative means under these conditions. Dr Merrill is to be congratulated on the conservative way in which he handled his case.

TRANSURETHRAL RESECTION OF THE INTERNAL SPHINCTER IN A CERTAIN TYPE OF CORD BLADDER*

BY EDWARD L. PEIRSON, JR., M.D.

THE classical cord bladder shows a marked loss of tone and sensation of the bladder wall with relaxation and funnelling of the bladder neck. There is, however, another type of neuro-pathic bladder which is seen in the presence of a minimal cord lesion. In this type, the tone and sensation of the bladder wall are maintained and the sphincters are spastic instead of relaxed. In such a case, one finds retention of urine due not so much to failure of the bladder musculature to contract and expel the urine as to failure of the sphincters to open properly during the act of voiding. The continued effort of the bladder to force out the urine through an uncooperative sphincter produces in the end, exactly the same state of affairs as would be produced by a bladder trying to force out the urine through an obstructing prostate or a contracted bladder neck.

My experience with this type of cord lesion has been limited to six proved cases in two of which I had an opportunity to examine the bladder at autopsy. An operation was performed on each of the six cases, the three advanced cases being treated by suprapubic cystotomy and three favorable ones by transurethral resection of the internal sphincter. The actual neurological diagnosis fortunately is not of great importance as we are interested in the functioning of the bladder and not in the cause of this dysfunction. It appears, however, that if the cord damage is extensive a different type of bladder lesion with loss of bladder tone will develop. The neurological diagnosis was central nervous system syphilis four cases, spina bifida one case and polyomyelitis one case.

The outstanding symptom, which brought all these cases to the hospital, was either acute or chronic retention of urine. The outstanding finding upon examination was a bladder which appeared characteristic of obstruction at the bladder neck without any visual evidence of organic obstruction. If the condition had been present for a long time as it had in the majority of the cases, a coarsely trabeculated bladder was found. In the three cases in which I had a chance to examine the bladder wall I found it very much thickened and identical with the type of blad-

der seen in long-standing prostatic obstruction. This is very different from the thin atonic bladder wall classically described as associated with cord lesions. The cystoscopic picture differed from organic obstruction in certain ways. Usually the interureteric ridge did not seem to share in the general hypertrophy. There was at least slight dilatation of the posterior urethra and as one looked inwards from the region of the verumontanum the internal vesical orifice appeared at least as wide open as normal. Five of the six cases showed definite dilatation of the upper urinary tract from back pressure and one case had a moderate-sized diverticulum.

There is obviously great danger in confusing this condition with actual organic obstruction such as median bar or contraction of the bladder neck. In fact I am inclined to believe that many cases which have been considered contracted bladder necks were in reality spastic internal sphincters. In certain cases, at least, it is impossible to make the differential diagnosis unless the internal sphincter can be directly examined with the finger, either under general anesthesia or at autopsy, as upon opening the bladder under local anesthesia the spastic internal sphincter may feel identical with a contracted bladder neck due to a chronic inflammatory condition. Likewise, as the nerve injury to the spinal cord is usually not extensive, the condition may not be obvious. Furthermore, there is some evidence to show that it may be possible to have retention of urine due to spasm of the internal sphincter without any cord lesion at all. Certainly, a very similar, although a transitory condition is frequently seen following a simple abdominal operation. In other cases, however, I have found it possible to demonstrate, without opening the bladder, that the retention of urine was due to sphincter spasm (or perhaps more accurately, to failure of the internal sphincter to open properly), and not to organic obstruction.

In spite of the fact that some bladder disturbance is found in the majority of cases suffering from disease of the spinal cord, the investigation of the urinary tract in these cases has frequently been overlooked. Often, the physician in charge of the case has failed to realize that the bladder symptoms may be the first and only sign of spinal cord disease, and that the management of the retention of urine may be the

*Read at the meeting of the New England Branch of the American Urological Association, Boston, February 14, 1935.

†Peirson, Edward L., Jr.—Assistant Urologist, Salem Hospital. For record and address of author see This Week's Issue, page 75.

most important factor in the care of these patients. The seriousness of this condition is well shown in our series. Four of our cases were extremely sick from renal insufficiency and sepsis of the upper urinary tract. The two cases that had an N P N of more than 100 before operation both eventually died in spite of some temporary improvement following suprapubic cystostomy. The history of these six cases show very clearly that treatment by occasional catheterization leads invariably to disaster. The retention of urine must, in these cases, as in cases of prostatic obstruction, be treated in some way which will give adequate relief of the back pressure on the upper urinary tract.

If the case has not been neglected I believe the retention of urine can be cared for by resection of the internal sphincter. I should like to report briefly the last case which I have operated on by this method as this case gives a very fair picture of the condition and is very similar to the other cases.

This case was a man forty-two years of age who entered the Lynn Hospital for the last time on October 26 1934. At the age of three the patient had what apparently was anterior poliomyelitis which had left

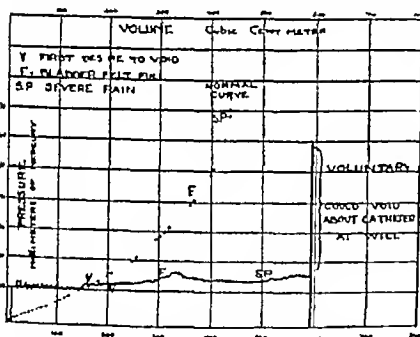

PLATE 1. Cystometrogram of the case described in this paper (August, 1932). It shows some lack of tone of the bladder musculature.

him a cripple with complete motor paralysis of both legs except for the big toe on the right foot. As a result, there was little or no development of the legs, marked scoliosis and deformity of the pelvis. Sensation of the legs sexual and urinary functions had been normal although the urinary stream had been poor. The patient's first urinary symptoms developed in March 1932. At this time he suddenly developed acute retention. I carried out a very careful urological examination and was unable to demonstrate any pathology in the urinary tract. After a few catheterizations he was again able to void. During the following two and one-half years the patient developed more and more urinary symptoms the outstanding one being repeated attacks of acute retention which always subsided and allowed the patient to empty his bladder after a period of catheter drainage. During this period there was increasing frequency and difficulty in urination. A diagnosis of cord bladder was made on purely nega-

tive evidence. During this period of time he was repeatedly admitted to the Lynn Hospital and was also studied by Dr. Richard Chute at the Baker Memorial Hospital where a cystometrogram was done which showed normal bladder sensation with some loss of tone of the bladder musculature (Plate 1).

On the last admission to the hospital in October 1934 he had acute retention of forty-eight hours duration with a greatly distended bladder. The prostate was small and indistinct and the tone of the rectal sphincter was normal. He was put on catheter drainage for two days, at the end of which time I cystoscoped him. It was surprising to find at this time that his bladder which two days before had held over forty ounces would now hold less than two and that he was able to empty his bladder completely. This marked variation both of the bladder tone and capacity and also in the patient's ability to void is I believe characteristic of the functional condition under consideration. Cystoscopic examination showed some trabeculation

PLATE 2. Urethrogram of a normal individual taken by injecting opaque solution backwards from the meatus.

of the bladder with considerable inflammation. No prostatic enlargement was seen and the posterior urethra was not elongated. The posterior urethra which previously had appeared normal, now appeared definitely dilated but the internal sphincter showed only slight dilation. Upon looking back toward the bladder neck with a panendoscope from the region of the verumontanum one could see clearly through the internal vesical orifice which was open wider than normally. The dilation of the posterior urethra made the floor of the urethra lower than the bladder neck and consequently the internal sphincter stood out prominently and one could easily have mistaken the sphincter for a median bar. Intravenous pyelograms made at this time and compared with plates taken two years before showed that marked dilation of the upper urinary tract had occurred in the meantime. There had likewise been a reduction in the urinary function.

At this time I obtained some nephrograms which I now wish to show. I previously found that urethrograms taken by injecting opaque solution backwards through the urethra often gave one a very false idea of the condition in the posterior urethra and bladder neck. Accordingly acting upon a suggestion of Dr. E. G. Crabtree, these nephrograms were obtained by filling the patient's bladder with an opaque

solution and taking the picture while the patient was voiding. For this purpose, I devised an emulsion of mineral oil, acacia and sodium iodide which was very satisfactory and much more economical than lipiodol. Plate 2 is a normal urethrogram taken by injecting the solution backwards from the meatus in the usual way. I wish you would compare it with plate 3, which is a urethrogram of the same normal individual taken during the act of voiding.

PLATE 3 Urethrogram of the same normal individual (Plate 2) taken while the patient was actually voiding. If one compares this with the previous plate, one observes the changes which normally occur at the bladder neck during the act of micturition.

You will notice that in plate 3 the bladder neck has opened widely to form a funnel, and that this has apparently been accomplished by a pulling downwards of the bladder neck so that the area of constriction in the internal sphincter and also the bladder floor is considerably lower than before. Presumably, this has been accomplished by

PLATE 4 Urethrogram of the case described in this paper taken during the act of voiding. One observes that the spastic internal sphincter obstructs the bladder neck. See text.

the action of the muscles which run from the trigone down the urethra. This demonstrates the importance of the fact, that the opening of the internal sphincter is an active and not a passive phenomenon and explains the retention of urine in these cases. It also explains why the retention is relieved by resection of the sphincter even if the sphincter is somewhat dilated before operation. In this plate both sphincters are well relaxed and there is a large stream passing through the urethra.

The third urethrogram (plate 4) is of the patient under discussion taken during the act of voiding. In spite of this, one observes that the internal sphincter has not relaxed. The bladder neck has not been pulled down and funnelled out. The posterior urethra appears dilated and the external sphincter, in spite of the fact that the patient is voiding, is not relaxed.

I think one can see from this how easily one might confuse the spastic internal sphincter with a median bar on cystoscopic examination. In fact, the failure of the internal sphincter to open actively has produced a condition nearly identical with actual obstruction at the bladder neck. The marked dilation of the posterior urethra and the lack of opening and depression of the bladder neck, seem to me, to be very striking and to prove conclusively that the retention of urine is due to spasm of the sphincter muscles and not to an obstructive lesion. Unfortunately, this plate is not very good, as the marked deformity of the pelvis made it difficult to get the patient squarely centered on the table.

The last plate (plate 5) is a urethrogram on this

PLATE 5 Urethrogram of the same patient obtained six days after operation. It shows the artificial funneling of the bladder neck which has been produced by resection of the internal sphincter.

same patient taken six days after transurethral resection of the internal sphincter. One observes here that action of the internal sphincter has been destroyed and the posterior urethra has become continuous with the bladder. This artificial funneling of the bladder neck has produced a condition not very different from a normal state of affairs during micturition as shown in the previous plate, the main difference being that the bladder base has not been pulled down. The external sphincter is still somewhat spastic but the greater force of the urinary stream has caused it to open more widely than before operation.

Following the taking of these urethrograms, the patient was taken off catheter drainage and observed for a week. For two days he was able to void well. Then he began to have marked frequency and difficulty in voiding. The stream became smaller and he passed only a small amount at a time. The residual urine increased daily until at the end of the week it amounted to six ounces. On November 6, I resected his internal sphincter with a McCarthy resectoscope removing three large pieces from the posterior and posterior lateral aspects. The pathological examination showed numerous muscle bundles so arranged as to suggest sphincter muscles. Immediately beneath the mucosa there were large clumps of lymphocytes and plasma cells.

Twenty-four hours after resection the patient was able to void easily and passed a large and more forceful stream than he had ever done in his life. He has continued to date to void easily and freely without residual urine. He has no incontinence. He gets up once at night and passes his urine about four times a day. A checkup cystoscopic examination shows the same funneling of the bladder neck as is seen in the postoperative urethrogram. The posterior urethra and bladder appear continuous.

The two other cases in which I have carried out this operation have been quite similar to the one reported. In both cases the neurological diagnosis was tabes paresis. Both cases came to the hospital with a large residual urine and were preoperatively treated by catheter drainage with as is common in these cases marked improvement in the bladder decompensation. It was not sufficient however to

leaving the hospital he gained twenty pounds in two months and was able to return to work which I think shows the great improvement which can be obtained with adequate bladder drainage in these cases.

As regards the operation it is extremely simple and very much more efficient in this type of case than any operation on the sympathetic nervous system. Such a small amount of tissue needs to be removed that it is truly a minor procedure. If the tone of the external sphincter is maintained (which can easily be determined by urethrograms or by observation) there is no danger of incontinence.

There is however, the theoretical possibility that there may be sufficient spasm of the external sphincter to prevent voiding even after resection of the internal sphincter. It is my experience however that if the internal sphincter is not markedly relaxed and the bladder tone has been sufficiently maintained, the operation will be successful. If however study of the case shows marked loss of tone of the musculature of the bladder wall or marked relaxation of either sphincter this operation is contra-indicated. As regards the permanency of the result, I know nothing as these cases have been followed only a short time. It seems reasonable to suppose that if the progress of the disease in the spinal cord cannot be checked they may develop further urinary complications. On the other hand if no further damage to the nerves of the bladder occurs I believe the results will be permanent and even if this is not the case, the improvement in these patients to date has been sufficient to justify the procedure. This type of patient must have adequate bladder drainage if his health is to be preserved. This can be obtained either by resection of the internal sphincter or by permanent suprapubic cystostomy. It seems logical to save the latter procedure for those cases which cannot be handled by resection of the internal sphincter.

DISCUSSION

DR. RICHARD CHUTE: I would like to compliment Dr. Peirson on his very real and ingenious contribution to this subject. I have been interested in this for some years and I do not think there is anything more puzzling than one of these neurological bladders.

allow them to empty their bladders even temporarily. The first case was operated on seven months ago. He came to the Salem Hospital with acute retention and a greatly distended bladder. He had had frequency and difficulty of micturition for three years. The urinary stream was small and he was known to have had some residual urine for several years. The findings were very similar to the case just reported. Following resection of the internal sphincter he has been able to void normally and has had no residual. He has slight frequency and urgency but no incontinence. The third case was operated on four months ago. He came to the Salem Hospital with twenty-four ounces of extremely foul residual urine and a bilateral pyonephrosis which was caused by the back pressure. There was more loss of bladder tone and more dilatation of the posterior urethra and internal sphincter in this case than in the other two. He was anemic and was running a septic temperature. After a period of catheter drainage a transurethral resection of the internal sphincter was carried out. His urinary stream has never been so forceful as in the other cases because of loss of bladder tone but he has been able to empty his bladder. In spite of the fact that he did not carry out the antineurotic treatment after

He spoke of one thing that I think is a conception which a lot of people have not yet acquired that is this business of decompensation and recompensation of the bladder. You take a bladder that has decompensated due to some sort of obstruction either neurogenic or prostatic and as in Dr. Peirson's case which had forty ounces of residual urine rest it with catheter drainage and allow it to recompensate and on recompensation it will only hold two ounces. If we bear that conception in mind it will often straighten out some of our bladder difficulties. Dr. Peirson's third case where this patient apparently did not have much pain in his bladder I should

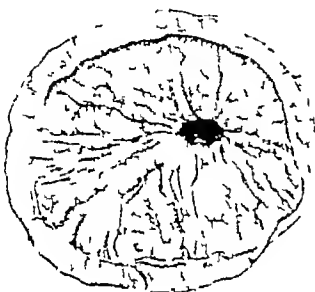

PLATE 4. Drawing of the bladder neck from an autopsy specimen of a patient with central nervous system syphilis.

The history and cystoscopic findings were similar to those reported in this paper. When the bladder neck was examined at the time of suprapubic cystostomy under local anesthesia it was found to be tightly closed and felt to the examining finger like a contracted bladder neck. This autopsy specimen shows however that the contraction of the bladder neck was neurogenic and not organic in origin. At autopsy the bladder wall was greatly thickened, there was marked dilatation of the upper urinary tract and a diverticulum was present.

think, if he started running a residual it might be a good thing to do a sympathectomy in combination with this, but, as Dr Peirson shows this is so much simpler and easier, I should think it would be a good thing to try

I was wondering about the rectal sphincter Was that also spastic?

DR F H COLBY This communication of Dr Peirson's is excellent It sounds a little too good to be true, that is all These cases have always been difficult problems

I wish to ask Dr Peirson if during the course of his endoscopic examination, viewing the internal sphincter, he asked these patients to try to void voluntarily and then stop voiding, whether he saw any movement of the internal sphincter, whether they could relax it or whether they could contract it to any extent

DR C J E KICKHAM Relative to the paper of Dr Peirson and the question of infection in his group of cases, I would like to ask whether the intractable chronic infection so frequently encountered in the urinary tract of the cord bladder individual affected the postoperative course in his cases Sepsis is the most common complication of transurethral resection and also the most important contraindication In view of this, it seems to me that this procedure might be quite hazardous in this type of case

DR G G SMITH I have been tremendously interested in this paper of Dr Peirson's There is one point I wish he would comment on in discussion In the cases of tabs that I have cystoscoped, I have always seen the bladder neck wide open so that even with an observation cystoscope you could look around the posterior urethra In other words, this funnel-shaped bladder neck seems to have already developed I would like to have him put me right about this and tell me whether they were more advanced cases or why I found that appearance to exist

DR CLYDE L DEXING There is one point which I do not quite comprehend and that is, why can one look through the internal sphincter of the bladder from the posterior urethra in these cases? I do not doubt that this is true but if it is true why should not the patient void? His urograms are convincing that there is something wrong

DR E L PEIRSON As regards Dr Colby's statement I should say that I tried seeing whether they could relax the bladder neck when I looked in with the endoscope I also tried it in one or two who were normal, and I was not convinced that I could tell one way or the other I think, as Dr Colby pointed out these results are much too good to last and I think I brought out the point that I do not know whether they will last We do know, however, with this type of cord bladder with increased bladder pressure that the patient will go on and die from sepsis and back pressure on the upper urinary tract if that pressure is not adequately relieved Something has to be done for them It seems to me it is entirely justifiable to do this operation for if it fails they can still have

the suprapubic cystotomy, but I think that treatment by pity and occasional catheterization is not justifiable

As regards infection as a complication, I think it is very important Because of the severe infection I did a suprapubic cystotomy in three of these cases In the one case which I resected which had a pretty bad infection, the infection had been fairly well cleared by catheter drainage before the operation was undertaken Such a small amount of tissue needs to be removed in this operation that infection does not play such a serious part as it does in resecting an adenoma of the prostate

As regards Dr Smith's question about the dilated bladder neck, I think when you consider the extreme complexity, the neurophysiology of the bladder and in addition, consider the diffuse and scattered nature of the lesions of the spinal cord that it is quite easy to conceive that by placing your lesions in the spinal cord at the proper place you can produce almost any type of lesion of the bladder You can have relaxation of the sphincter or spasm, you can have increased or reduced tone of the bladder wall At the present time, I have in the Salem hospital a case exactly like the one Dr Smith speaks of, with acute retention, a large residual urine, infection and marked funnelling of the bladder neck, with spasm of the external sphincter so that he is unable to void That shows up nicely in the urethrograms when we fill up the bladder and he tries to hold it, the urine comes down to the external sphincter In other words, the whole posterior urethra is tremendously dilated That type of case is obviously unsuited for this form of treatment.

Perhaps the confusion is that I was speaking of looking back from the verumontanum using the McCarthy panendoscope with the fore-oblique vision You look back from the verumontanum into the bladder neck just as you can with the resectoscope Of course the prostatic urethra in these cases is very short and you can see the bladder quite clearly with the panendoscope The reason they can void after you have resected the internal sphincter, although the internal sphincter was open before you resected it, is, I think, quite clearly shown in the third urethrogram which I showed In this urethrogram the internal sphincter stood out quite clearly as a definite band at the bladder neck which would cause obstruction to the outflow of urine just as a chronically inflamed, hard, and rigid bladder neck causes obstruction In either case, the opening of the bladder neck may be of sufficient calibre to allow the outflow of urine, yet retention may exist because of the bar of tissue posterior to the internal meatus which fails to relax at the time of micturition

The surprising thing was, it seems to me, that the other neurological findings were very slight In some cases the rectal sphincter was relaxed In some we found a few other neurological signs such as absent or hyperactive knee jerks, absent corneal reflexes in two cases, and fixed pupils in two cases But by and large the neurological signs were quite striking by their absence, although the findings in the spinal fluid were very definite in all the syphilitic cases

THE RECURRENCE OF BENIGN OBSTRUCTING PROSTATES YEARS AFTER PROSTATECTOMY*

BY RICHARD CHUTE, M.D.†

A SUCCESSFUL prostatectomy on a benign hypertrophied obstructing prostate has always been carried with it the thought of a permanent cure and urological surgeons are wont to say to their patients, "Well, old man, it's all out now and it'll never bother you any more." They are right in more than 99 per cent of the cases, but not in 100 per cent, for on rare occasions regrowth of the benign hyperplastic prostatic tissue will take place to the extent of causing typical prostatic obstruction again. I would like to report two such patients from whom I have removed good sized, benign, obstructing, "regrown" prostates in the last few months, patients on whom my father had performed successful prostatectomies ten years and eighteen years before respectively.

The first patient was fifty-nine years old when my father operated on him in 1924. At that time he gave a five months history of difficult urination with frequent desire etc. and he had six ounces of infected residual. By rectum his prostate felt perfectly benign and was not markedly enlarged. A one-stage suprapubic prostatectomy was done and three small masses largely intraurethral were enucleated in the usual manner without any difficulty. The microscopical report was benign hypertrophy. The patient made a satisfactory recovery, and had been without urinary symptoms for ten years until a few months before I was called to see him last August after two episodes of acute retention. His prostate by rectum felt somewhat larger than normal and absolutely benign. Cystoscopy showed a marked anterior cleft and more or less encroachment of the prostate in the median region, also marked trabeculation. Eye reflexes and knee jerks were normal. After the usual preparation, I did a one-stage suprapubic prostatectomy easily enucleating a moderate-sized benign prostate in one piece consisting of both lateral lobes. The pathological report on this was benign hypertrophy. The patient made a satisfactory convalescence and I have seen him recently. He voids with perfect control and has practically no residual urine.

The second patient was only forty-seven years old when my father operated on him in 1916. Father saw him in his second episode of acute retention with his bladder up to his umbilicus and withdrew thirty-one ounces of turbid urine. The patient gave a history of painful difficult urination for about a year, his stream was very slow and painful to start, and he passed only a little urine at one time. His prostate by rectum felt slightly enlarged and benign. Cystoscopy showed the prostate jutting in on all sides especially on the right, with some trabeculation and also a small diverticulum of the bladder. Knee jerks and eye reflexes were normal. Father did a one-stage prostatectomy shelling out a somewhat enlarged prostates in the usual manner

and not touching the small diverticulum. The patient made a satisfactory convalescence and ended by voiding with perfect control with only one-half ounce of residual urine. After the operation the patient was fine for nearly fifteen years but in the last three years had had mild symptoms of recurrent prostatism: a few ounces of residual urine had begun to accumulate and rectal examination revealed considerable benign regrowth of his prostate. Last October I was called to see him in acute retention and withdrew twenty-six ounces of residual. His prostate by rectum was considerably enlarged and it was necessary to depress the cystoscope markedly in order to pass it over the raised bladder outlet and cystoscopy showed considerable prostatic tissue jutting in the median and lateral regions. Knee jerks and eye reflexes were normal. I did a two-stage suprapubic prostatectomy on him easily enucleating in one piece a good sized prostate which weighed fifty grams. The pathological report was benign hypertrophy. He made a satisfactory recovery and I have seen him within a month. He voids with perfect control and empties his bladder practically completely.

These two cases meet the requirements for genuine benign recurrence so well expressed by Victor Blum of Vienna² who feels that only those cases should be classed as genuine recurrences in which after a properly and carefully performed perineal or suprapubic prostatectomy and after an interval of several years during which there is normal micturition the symptoms of prostatic obstruction reappear, and a recurrent prostatic hypertrophy is definitely present by rectal examination and cystoscopic inspection or through the opened bladder and in which there is not the slightest suspicion of malignancy.

I have looked through a good deal of the world literature on this subject and have found less than fifty cases which fulfill the above requirements for genuine recurrence of benign obstruction. A good many cases have been reported in which considerable regrowth of the prostate some time after prostatectomy has been evident on rectal palpation or on postmortem examination, but there have been very few of these cases reported which gave urinary obstruction again during life. We have not the time to consider the various theories as to the place of origin, and mechanism of growth of benign prostatic hypertrophy but according to the best opinions at the present time the hyperplastic growth probably starts in the submucous periurethral groups of prostatic glands situated in the region of the neck of the bladder. As these centrally placed glands of the prostate undergo hypertrophy and grow, they form an expanding adenomatous mass which presses on the outer layer of prostatic glands which gradually atrophy and become flattened and form the so

*Read at the meeting of the New England Branch of the American Urological Association, Boston, February 11, 1935.

†Chute, Richard—A urologist, Massachusetts General Hospital. For record and address of author see "This Week's Issue," page 15.

called "surgical capsule" of the prostate. The ordinary enucleation of the prostate is not really a complete prostatectomy, it is merely the separation of one part of the prostate from another part of the prostate along an easy plane of cleavage. It is the shelling-out of a tumor mass composed of the hyperplastic central glands of the prostate from the so-called "capsule," which is composed of the flattened and atrophic outer prostatic glands and is left behind. This is a well-known fact of long standing. As to the theories as to the cause of regrowth, one is that the flattened atrophic outer glands of the prostate which formed the capsule may, in the course of time, take on new life, proliferate and occasionally undergo enough hyperplasia to form another obstructing growth after the removal of the adenoma of the central glands which had been making pressure on them. It has also been shown by various men^{2,3,4} that after prostatectomy very small nodules of hyperplastic tissue often only recognizable under the microscope, can frequently be found in the surgical capsule and it is thought by some that these hyperplastic nodules continue their growth and eventually may produce a recurrent obstructing mass.

The average age of the patients in my series was sixty years at the time of their first operation. This is more than five years younger than the age of the average prostatic operated upon in the Massachusetts General⁵ and Johns Hopkins⁶ hospitals and it may be that it signifies that these patients have prostatic cells which have greater vitality and tendency to proliferate than the average so that they get their masters into trouble five years earlier than the average prostatic and then are hard to eradicate, and stubbornly regrow again after operation like hardy perennials. It seems likely that there may be some endocrine gland factor, not understood at present. The clinical recurrences in my series appeared on an average of seven and a half years after the first operation.

SUMMARY

The paucity of reports of true recurrent benign prostatic obstruction is very hard to explain considering the thousands of prostatectomies that have been performed since the turn of the century, but I do wish to call your attention to the fact that genuine benign recurrences following prostatectomy occasionally occur and to report two personal cases that recurred ten years and eighteen years respectively after their original operations.

DISCUSSION

DR E L MERRITT. I recall that several years ago at a clinic given by Dr Squier in New York, he called attention to the necessity of removing all of the small spheroidal bodies, as he called them, at the time one did a prostatectomy and in the particular case he was operating upon at that time he removed a fairly large, adenomatous prostate and then he reached down into the prostatic fossa and removed quite a long chain of these hyperplastic nodules, as Dr Chute called them. Several times since then, in doing prostatectomies, I have reached down into that fossa following the removal of the gland, finding quite a long chain of these small nodules and I have recalled that Dr Squier brought out the fact that if they were left he felt quite confident that they would cause recurrence. I wonder how the other men feel about that.

DR HAROLD S BACKUS. I was especially interested in this paper because when I first took up the study of Urology there was a very prominent surgeon who did a secondary prostatectomy ten years after the first prostatectomy, for which he got \$5000. That interested me, thinking I might be able to make a living doing Urology. Also, about fifteen years ago before Prof Hugh Cabot went west urologically, one of the first things I heard him say, in one of his lectures, was, "We do not remove the prostate, we just remove the adenomatous growths and there is no reason why they cannot grow again." For that reason I was interested to know that they do grow again.

I find, in doing prostatectomies, that there is quite often considerable prostatic tissue left after the growths have been enucleated. I do not try to get it out, if it causes no obstruction. However, I believe this tissue may hypertrophy and cause trouble in a few cases.

DR CLIDE L DEMING. In New Haven we have been studying prostatic hypertrophy for a couple of years and we have a hunch as to why these recur. We feel that prostatic hypertrophy arises from the glands of the posterior urethra, that it arises from the lateral lobes of the true prostatic gland and that it arises from the glands between the verumontanum and neck of the bladder deep in the prostate. It is reasonable to expect that a greater number of these hypertrophies arise from the glands of the posterior urethra. If these are removed primarily we do not in any way interfere with the other multiple foci for prostatic development deep in the prostatic gland.

DR CHUTE. As to Dr Merritt's remarks, I think it is a very good point about the spheroidal bodies which you occasionally see and I, for one, from now on am going to try to do more one-stage suprapubic prostatectomies because when you reach down through the typical sinus in the second stage operation while you can do a pretty good job, you don't have the flexibility that you do with a one-stage prostatectomy when you have things wide open and can view and explore the prostatic bed pretty thoroughly, and I think on the basis of this, I shall try to do more one-stage operations.

DR BACKUS speaks of the matter of the big fee. Of course, there is the possibility that a very mean patient who had a recurrence after a few years

might sue you especially if he had paid a good fee in the first place. He might claim that the operation had been badly done and it is conceivable it might cost you quite a bit and also a loss of reputation if it got into the newspapers.

As for Dr. Deming's remarks that discussion is so involved that I won't try to go into it. I was

morely stating things as I saw them but I know that Thompson Walker in London and others would agree with you on that. But the big wonder of it all to me is the fact that there must have been 100,000 prostatectomies done since 1900 and I can only find fifty reports of genuine recurrences in the literature.

CYSTS OF THE TESTICLE*

BY RALPH H. JENKINS, M.D.† AND CLYDE L. DEMING, M.D.†

CYSTS of the testicle are classified into cysts of the tunica albuginea and cysts of the testicle. They are exceedingly rare. In reviewing the literature it is difficult to separate simple cysts of the testicle from cystic neoplasms. Sir Astley Cooper¹ in 1845, described the gross anatomy of teratoma of the testicle under the term of hydatid disease. This article was elaborately illustrated and four cases of simple cysts were described. Curling² in 1853 divided the growths into cystic, relatively benign, and solid malignant tumors. He described two such cases as simple cysts. Ewing³ in studying the reports of Cooper and Curling felt that their cysts were of neoplastic origin. Succeeding accounts were less accurate in differentiating cyst of the testicle and cystic neoplasms. Cases were described, however, by Hochenegg⁴, 1885 and Waliman⁵, 1911. Albert⁶ 1893, mentions three cysts of the testicle in 6000 autopsies.

C. K. Smith⁷, in 1919 reported a large cyst of the testicle which he believed followed gonorrhea. He suggested that the etiology was an occlusion of the vas deferens and epididymis following epididymitis resulting in a cystic condition of the epididymis and secondarily involving the testicle.

Barach⁸, in 1919, reports a very interesting case of cyst of the testicle in a dog. He considered trauma as the etiological factor as this dog was run over by an automobile four or five years previous to his operation.

K. Frater⁹, in 1929 reported and illustrated a case of cyst of the tunica albuginea. The cyst measuring 1 cm. in diameter contained clear fluid and was located in the anterior surface of the left testicle near the upper pole. The walls of the cavity appeared to be complete. The rest of the testicle showed little change. The epididymis was normal. The inner surface of the wall was lined in some parts by a single layer of cells and in others two or more. The nuclei of these cells were slightly ovoid. There was no history of gonorrhea, injury or abnormality

of the testicle. The urine contained four pus cells to the high power field. The Wassermann reaction on the blood was negative. The patient died from pernicious anemia.

Simple cysts of the testicle should not be confused with an encysted hydrocele of the body of the testicle. The latter is a small collection of serous fluid beneath the visceral portion of the tunica vaginalis which according to Rose and Carless¹⁰, is probably due to the dilatation of the lymphatic spaces and has no clinical significance.

The case reported here is a cyst of the testicle.

A man twenty-eight years of age was referred by his family physician to Dr. Clyde Deming for impotency. He had indulged in an active sexual life which consisted of intercourse five times daily since his marriage four years ago. During the past two months he was only able to have intercourse about once in five days due to the lack of erections. There were no premature ejaculations and no other symptoms other than that he complained of being weak and tired following intercourse. There was no history of gonorrhea, injury or abnormality of the testicles.

Our examination was entirely negative except that a hard painless somewhat irregular mass measuring 2 x 3 cm. was found involving the lower lobe of the right testicle. This mass did not transmit light. The right epididymis and vas deferens were normal in size and consistency. The left scrotal contents were normal. The urine was normal. The prostatic and vesicular fluids were normal. The Wassermann reaction on the blood was negative.

The patient was seen a few weeks later and the mass in the testicle had apparently increased in size. Our diagnosis was tumor of the testicle. An orchidectomy was performed under local anesthesia and the patient made an uneventful recovery.

Our surgical pathologist, Dr. Béla Halpert, gave the following pathological report:

"Gross. The specimen consists of the right testicle, epididymis and a part of the spermatic cord enclosed in the tunica vaginalis communis. The cavity of the tunica vaginalis contains no excessive fluid and its surfaces are smooth and shiny. The testicle and epididymis are of normal size and shape and measure 5.5 x 3 x 3 cm. In the lower pole of the testicle there is a firm area beneath the capsule. The cut surfaces present the usual pattern except in the lower third where an amorphous laminated structure occupies an oval area 2.4 x 1.6 mm. The area is well circumscribed, appears to have a capsule and is soft in the center and quite firm in the periphery. It is gray and translucent while the rest of the surface is light orange-yellow.

Microscopic. The seminiferous tubules are

EDWIN KLEBS*

A Centennial Note

BY LEONA BAUMGARTNER, M D †

I. LIFE

EDWIN Klebs, whose hundredth birthday fell on February 6 1934, was one of the pioneers of bacteriology and he also made distinguished contributions in other fields of medicine. It therefore seems appropriate, at this time, to recall some of his achievements. The name of Klebs is irrevocably attached to the bacillus he first described in 1883 as found in the throats of patients with the then undifferentiated group of conditions called "croup"²². Less well known are many other contributions of almost equal significance. Thus he described acromegaly⁶ before Pierre Marie, fifteen years before Metchnikoff he inoculated primates with the virus of syphilis^{11 22 23}, he¹⁵ described the isolation of colonies of bacteria on solid media before Koch, he was the first to produce tuberculosis experimentally in animals by the injection of milk from infected cows, thereby establishing the bovine origin of the disease⁷, and he described typhoid bacilli and attributed a causal relation between the organisms and the disease before Eberth, who is generally accredited with their discovery. The establishment of priority *per se*, however can seldom be a matter of as great concern as the estimation of the influence exerted by a man upon the history of a given subject, and it is from this point of view that we propose to take up the work of Edwin Klebs.

Theodore Albrecht Edwin Klebs was born February 6 1834 in the decade of the nineteenth century which saw the birth of Johannes Müller's "Physiologie", Cruveilhier's school of pathological anatomy, and the cell theory of Schleiden and Schwann. It is perhaps not surprising, therefore that as he grew to manhood and finished school in his native Königsberg he turned to medicine instead of to the law to which the fortunes and traditions of his family had long been bound. Rathke, Helmholtz, Burdach, and Werther were his first teachers during five semesters in Königsberg. At twenty-one years of age he enrolled for further study at Würzburg under the then popular and stimulating medical faculty composed of Virchow, Kolliker, Scherer, Bamberger, Leydig and Seanzoni. In later years Klebs often spoke of these days in glowing terms. Virchow impressed him so deeply that at the first opportunity he followed him to Berlin as an assistant. This was in 1861 three years after the "Cellularpathologie" had appeared and after Klebs had completed his doc-

torate. A brilliant group was then gathered in the laboratories of Virchow's newly erected Pathological Institute. Edwin Klebs, Oskar Liebreich, Julius Cohnheim, Friedrich von Recklinghausen, Willy Kuhne, and Ernst Leyden, men who were unconsciously fitting themselves to occupy in later years the chief academic posts in the German-speaking medical world, and who already had commenced the researches which were to give to the school the credit of formulating the theories which dominated pathology for the next half century.

After these preparatory years Klebs went first to Berne (1866), then as Recklinghausen's successor to Würzburg (1872), and the following year to Prague at Heering's request, returning to Zurich, Switzerland, in 1882. The six years at Berne he described as the happiest of his life but the nine at Prague were the most fruitful scientifically. He not only did original work of first importance in bacteriology, but in addition he taught many young men, and developed three important medical journals. Among his pupils in these academic years were numbered Ernst Ziegler, Zahn, Hanau, Szarka, Koster, Fischl von Jaksch, Eppinger, and Lubarsch. It was the day of the founding of the great German scientific journals, journals so intimately bound up with their individualistic founders as to bear their names (Virchow's, Ziegler's, Pfugler's, etc.). The three journals which Klebs himself inaugurated were named in a style more approved by a modern scientific world which does not so readily countenance great individualism. *Die Prager medizinische Wochenschrift* begun in 1876, the *Correspondenz-Blatt für Schweizer Aerzte* appearing in 1871, and the *Archiv für experimentelle Pathologie und Pharmakologie* founded with Naunyn and Schmiedeberg in 1873. All have withstood the rigors of passing fashions in scientific publishing and have served a useful purpose for their respective readers.

Upon leaving Zurich, where he had worked for eleven years, Klebs went in 1893 to Karlsruhe for a year, then came to America, settling (1895-96) in the laboratory of a private tuberculosis sanatorium in Asheville, North Carolina, and in August of 1896 moving to Chicago as professor of pathology in Rush Medical College. But in 1900 he returned to Europe to live successively in Hanover (where the *Kausale Therapie*, the fourth and only short-lived medical journal edited by Klebs, was started), Berlin, Lausanne, and Berne. The many vicissitudes of his life, so often rendered poignant and even dramatic by the changeable temperament of the man, have been adequately commented upon by his

EDWIN Klebs, whose hundredth birthday fell on February 6, 1934, was one of the pioneers of bacteriology and he also made distinguished contributions in other fields of medicine. It therefore seems appropriate, at this time, to recall some of his achievements. The name of Klebs is irrevocably attached to the bacillus he first described in 1883 as found in the throats of patients with the then undifferentiated group of conditions called "croup."²⁰ Less well known are many other contributions of almost equal significance. Thus, he described acromegaly⁶ before Pierre Marie, fifteen years before Metchnikoff he inoculated primates with the virus of syphilis¹¹⁻²³, he¹⁵ described the isolation of colonies of bacteria on solid media before Koch, he was the first to produce tuberculosis experimentally in animals by the injection of milk from infected cows, thereby establishing the bovine origin of the disease¹⁷, and he described typhoid bacilli and attributed a causal relation between the organisms and the disease before Eberth, who is generally accredited with their discovery. The establishment of priority *per se*, however, can seldom be a matter of as great concern as the estimation of the influence exerted by a man upon the history of a given subject, and it is from this point of view that we propose to take up the work of Edwin Klebs.

Theodore Albrecht Edwin Klebs was born February 6 1834 in the decade of the nineteenth century which saw the birth of Johannes Müller's "Physiologie", Cruveilhier's school of pathological anatomy, and the cell theory of Schleiden and Schwann. It is perhaps not surprising, therefore, that as he grew to manhood and finished school in his native Königsberg, he turned to medicine instead of to the law to which the fortunes and traditions of his family had long been bound. Rathke, Helmholtz, Burdach, and Werther were his first teachers during five semesters in Königsberg. At twenty-one years of age he enrolled for further study at Würzburg under the then popular and stimulating medical faculty composed of Virchow, Kolliker, Scheer, Bamberger, Leydig and Scanzoni. In later years Klebs often spoke of these days in glowing terms. Virchow impressed him so deeply that at the first opportunity he followed him to Berlin as an assistant. This was in 1861 three years after the "Cellulärpathologie" had appeared and after Klebs had completed his doc-

torate. A brilliant group was then gathered in the laboratories of Virchow's newly erected Pathological Institute. Edwin Klebs, Oskar Liebreich, Julius Cohnheim, Friedrich von Recklinghausen, Willy Kühne, and Ernst Leyden, men who were unconsciously fitting themselves to occupy in later years the chief academic posts in the German-speaking medical world, and who already had commenced the researches which were to give to the school the credit of formulating the theories which dominated pathology for the next half century.

After these preparatory years Klebs went first to Berne (1866), then as Recklinghausen's successor to Würzburg (1872), and the following year to Prague at Heering's request, returning to Zurich, Switzerland, in 1882. The six years at Berne he described as the happiest of his life, but the nine at Prague were the most fruitful scientifically. He not only did original work of first importance in bacteriology, but in addition he taught many young men, and developed three important medical journals. Among his pupils in these academic years were numbered Ernst Ziegler, Zahn, Hanau, Sazka, Koster, Fischl, von Jaksch, Eppinger, and Lubarsch. It was the day of the founding of the great German scientific journals, journals so intimately bound up with their individualistic founders as to bear their names (Virchow's, Ziegler's, Pflugler's, etc.). The three journals which Klebs himself inaugurated were named in a style more approved by a modern scientific world which does not so readily countenance great individualism. *Die Prager medizinische Wochenschrift* begun in 1876, the *Korrespondenz-Blatt für Schweizer Aerzte* appearing in 1871, and the *Archiv für experimentelle Pathologie und Pharmakologie* founded with Naunyn and Schmiedeberg in 1873. All have withstood the rigors of passing fashions in scientific publishing and have served a useful purpose for their respective readers.

Upon leaving Zurich, where he had worked for eleven years, Klebs went in 1893 to Karlsruhe for a year, then came to America, settling (1895-96) in the laboratory of a private tuberculosis sanatorium in Asheville, North Carolina, and in August of 1896 moving to Chicago as professor of pathology in Rush Medical College. But in 1900 he returned to Europe to live successively in Hanover (where the *Kausale Therapie*, the fourth and only short-lived medical journal edited by Klebs, was started), Berlin, Lausanne, and Berne. various necrologists^{1 3 4 5 7 8 9 10 11 12 13}, but his work gives little or no evidence of restlessness or indecision of thought

II. WORK

His early studies on the bacteriology of gun shot wounds^{14 15} growing out of his experiences in 1870 and 1871 in military hospitals in Carlsruhe and antedating by one year Koch's great memoir on the subject, had convinced Klebs of the bacterial nature of wound infection. He immediately devoted himself to impressing the ardent followers of the Virchow school of the importance of these external agents. These antagonists of humoral pathology, engrossed in the myriad of fresh vistas which new histological methods were bringing beneath their microscopes (Klebs' paraffin-embedding¹⁶, Cohnheim's frozen sections, etc.), found it difficult to accept the bacterial theory of infection and to Edwin Klebs must be given a large share of the credit for winning them over to this view. His own bacteriological studies included a treatise on the cause of anthrax¹⁷ appearing a year after Koch's work, the first description of the bacillus of typhoid fever¹⁸ and of diphtheria¹⁹ and extended studies on cholera^{20 21 22} and malaria^{23 24 25}. The use of solid media in the form of sturgeon's glue was fully described by Klebs in 1872²⁶ nine years before Koch. But Klebs saw in the method not a means of separating bacterial species, as did Koch; he was interested in the different colonies as different stages in the growth of the same organism, an interesting observation in view of the recent ideas concerning bacterial dissociation. He felt he could secure pure cultures with his method of fractional dilution, i. e. killing off the contaminants in an impure culture by successive transfers through a series of fresh media. The Koch postulates, first enunciated in 1882 had certainly been foreshadowed in Klebs' statements *modo* in 1877 concerning the etiology of tuberculosis²⁷. Having discussed the anatomy of the local lesion, he pertinently remarks

"The simplest way to prove that the cells of the diseased animal neither produce nor in any way increase the virus of tuberculosis is to cultivate it outside of the organism under conditions which do not destroy the life processes of the cells of the warm blooded hosts. If under such conditions, there is still an increase in the toxic action this must be dependent upon the presence of tissues of the animal body remains of dead tissue cells, or upon components of the inoculum which usually foreign to the animal, developed within the tubercle." (a)

(a) "Der einfachste Weg um zu beweisen, dass nicht die Zellen des erkrankten Thieres den Giftstoff der Tuberculose produciren oder zu seiner Vermehrung irgendwelche Beiträge liefern, besteht in der Cultivirung dieses letzteren ausserhalb des Organismus, unter Bedingungen, welche die Lebensthätigkeit der Zellen des Wirthes vernichten. Sind unter solchen Bedingungen dennoch ein Zunehmen der giftigen Wirkung statt, so kann dieses nur entweder von dem noch vorhandenem Bestandtheilen des Thierkörpers, oder von Bestandtheilen des Inoculums abhängen, welche dem Thierkörper ursprünglich fremd sind, innerhalb des Tuberkel entwickelt haben."

Having described cultivation experiments, using fresh egg white as a culture medium, he continues

"If it can thus be established, as the older inoculation experiments indicated and the ones presented today corroborate, that tuberculous infection can not only be induced by inoculation of tuberculous tissues but also with organisms which are found in such tissues and can be grown outside the body, it becomes necessary to establish the presence of these organisms in the diseased tissues from human and animal tuberculosis." (b)

And in proof of such a proposition he describes at length the organisms he has seen in tubercles. The final step of animal inoculation with culture virus is concisely outlined

Small amounts of the products of this cultivation experiment inoculated into the peritoneum of healthy animals result in the development of a milky tuberculosis exactly as does the implantation of tuberculous tissue in the same locus." (c)

It is of more than passing interest that in the discussion which followed the reading of the paper no comment was aroused over these experimental results for it is evident that they include the salient points of the well known Koch postulates upon which the recognition of any organism as the etiological agent of a given clinical entity has subsequently been based.

Klebs continued to be absorbed in the problem of tuberculosis during his entire life. His inaugural dissertation and first published work had been entitled *De mutationibus quae in intestino inveniuntur tuberculosis*²⁸ and he wrote over seventy individual articles²⁹, largely concerning the therapy of the disease. The one of greatest interest at present in view of the recent BCG vaccination method is that description of the use of attenuated strains of tubercle bacilli from cold blooded animals, in the development of active immunity in guinea pigs and human beings³⁰. His experimental production of the disease with milk of bovine origin has already been noted (d).

His many contributions to the field of path

(b) "Wenn hierdurch auch die Thatsache wohl zu feststeht, dass tuberculöse Affectionen nicht allein, wie die älteren Impfversuche lehren und die heute vorgelegten Präparate von Kulturen bestätigen, durch Uebertragung von tuberculösen Geweben sondern auch durch Organismen entstehen kann, welche aus solchen Geweben stammen und ausserhalb des Körpers sich vermehren können, so fordert diese Erfahrung doch wiederum auf, den Nachweis dieser Organismen in dem erkrankten Gewebe bei getrennter Tuberculose der Menschen und Thiere zu versuchen."

(c) "Gerade bei Menschen von den Produkten dieser Culturen ausserhalb der Bauchhöhle von gesunden Thieren eingespritzt, führten ebenso zur Erzeugung von miliarer Tuberculose des Peritoneums, wie dieses der Fall ist, wenn man genuine Tuberculen in dem gleichen Orte implantiert."

(d) It is unnecessary to include all of Edwin Klebs' printed work in view of the excellent bibliography of his scientific writings prepared by his son, Arnold C. Klebs³¹ which with its convenient classification of titles according to their contents, i. e. (1) normal and pathological anatomy and physiology (2) pathological etiology (3) prophylaxis and therapeutics (4) historical material and reviews (5) texts and (6) periodical contains about two hundred and twenty five titles. We were able to locate only a very few additional items and only one of any importance.

MEDICAL PROGRESS

PROGRESS IN PSYCHIATRY FOR 1934

BY KARL M. BOWMAN, M.D.*

DURING the past year there has been continued work in formulating a plan to provide some type of certification for qualified psychiatrists. This has finally resulted in combined action by The American Psychiatric Association, The American Neurological Association and The Section on Neurology and Psychiatry of the American Medical Association. As a result a meeting was held in New York on October 20, 1934 at which the American Board of Psychiatry and Neurology, Inc., was organized. The following officers were elected:

Dr H Douglas Singer, President
Dr C Macfie Campbell, Vice President
Dr Walter Freeman, Secretary-Treasurer

Other Members of the Board are the following: Dr Lewis J Pollack, Dr George W Hall, Dr Franklin G Ebaugh, Dr Lloyd H Ziegler, Dr J Allen Jackson, and Dr Adolf Meyer. This Board will have authority to issue a certificate indicating that the individual is a qual

ified psychiatrist or neurologist or both. Psychiatry and neurology have by this step set up certain standards for a qualification and are following the example of a number of the other specialists in working out a plan to prevent unqualified persons posing as specialists in a particular field.

The annual meeting of The American Psychiatric Association was held at New York City May 29-June 1 1934. Prior to this meeting the National Committee for Mental Hygiene again arranged a two-day conference on "The Teaching of Psychiatry in Medical Schools." This conference again stressed the importance of psychiatry in the curricula of the medical schools and considered plans for improving such teaching.

There were apparently two points of view which showed considerable divergence.

One group felt that the teaching of psychiatry to medical students should be largely through the use of general medical and surgical material in which the psychological factors of physical disease were stressed. Certain members of this

*Bowman, Karl M.—Chief Medical Officer Boston Psychopathic Hospital 1921. For record and address of author see "This Week's Issue" p. 75.

ological anatomy and physiology included the first experimental production of valvular disease of the heart¹⁸ and the recognition of the bacterial infection in the production of the subsequent endocarditis²¹, his description of hemorrhagic pancreatitis as a rapidly fatal disease¹⁴, the introduction of the paraffin embedding method¹³, and his monumental texts, *Handbuch der pathologischen Anatomie*¹⁴ (1869-1876) and *Die allgemeine Pathologie, oder die Lehre von den Ursachen und dem Wesen der Krankheitsprocesse*²⁹ (1887-1889) which, though never completed, became invaluable source books for pathologists for the next twenty-five years. To the general understanding of the processes of cell necrosis with its phases of karyolysis and karyorrhexis, of infarction, thrombosis and embolism he added much that was illuminating.

It is commonly conceded that Pierre Marie first described the clinical entity acromegaly which is still recognized by the name he so aptly coined. Of Klebs' several biographers² only Garrison³ draws attention to the fact that Klebs' paper on gigantism⁶ furnishes a complete and excellent description of the same disease, which antedates that of Pierre Marie by two years. Marie's classical description, appearing in the *Revue de Medicine* in 1886³⁰, was concerned with the clinical aspects of the two cases of the disease he had seen simultaneously in Charcot's clinic with notes on five apparently similar cases which he collected from the literature. No suggestion was made of the relationship of the disease to the pituitary gland, neither case having come to autopsy at this time. Marie was content to speculate on the possible etiology of the disease considering such widely divergent explanations as an involvement of the sympathetic nervous system, a generalized disease simulating rheumatism or a developmental defect. Klebs and his clinical collaborator, Fritzsche, describe in detail one case, Klebs being responsible for the painstaking and excellent postmortem descriptions, which in themselves are models of the careful work produced by the well trained pathologist of the nineteenth century. Moreover armed with the pathological findings Klebs proceeded to explain the etiology of the condition in broad physiological terms of growth and development, concluding that a generalized process of hypertrophy was at work, the pituitary hyperplasia being a manifestation of that process and the thymus being definitely involved. It is also interesting to see that he was the first to recognize that pituitary tumors had been associated with similar cases reported in the literature a point overlooked by Pierre Marie.

III CHARACTER AND INFLUENCE

That Klebs did not push many of his investigations to what to us seems then logical conclusion becomes apparent as soon as one sur-

veys his work. This was a natural failing of early pioneers. They moved in many entirely new fields, and they moved rapidly from one to the other. Klebs described the typhoid bacillus, but it was left for Gaffky to cultivate it four years later. The work on toxicity and non-infectivity of bacterial filtrates¹⁶ ¹⁸ was clearly of great significance, but it was not until years later that von Behring, Roux, and Yersin were to clarify the action of toxins and antitoxins. Some of these apparent shortcomings may well have been the result of his restless nature, which always interested itself in new aspects of a problem and was often impatient of the necessities of the moment. Several anecdotes give evidence of these tendencies. Dr. Welch repeatedly told a characteristic story illustrating this trait in Edwin Klebs. On the occasion of a visit by Klebs to Welch's laboratory at Johns Hopkins, Welch placed under several microscopes a series of preparations from a case of Landry's paralysis in which some of the thrombotic changes Klebs had first described were beautifully demonstrated. Welch said that he found Klebs looking into one after the other with but little comment. When pressed for some expression, he replied, "Evidently very good preparations, but those thrombi do not interest me any more. As I was looking at these cells I realized how much we have still to learn about the entire mesoderm." And at least two of Klebs' recorded statements give evidence that he recognized his own tendencies. One is a direct reply to a criticism hurled at his first announcement of the discovery of the diphtheria bacillus at the Second Congress for Internal Medicine held in Wiesbaden on April 19, 1883. To Dr. Korte of Berlin, who suggested that the question of etiology could be settled only after the organisms had been isolated in pure culture and then successfully inoculated into animals, Klebs replied (Reference p 172 of No 26) "I admit that I have devoted my efforts to this task for years, but gentlemen, he who works a great deal has many failures and, after any one of us has worked twenty-five years in this field, he cannot be blamed if he does not successfully achieve the desired goal." In later years, however, he is reported by one of his students to have said "I was the first to see and partially describe many pathogenic bacteria, but I had no success with those methods which yielded conclusive evidence. And everything depends upon these methods a basic idea in modern scientific research. Never fail to search for new methods." And it is as a pathfinder, always searching for the new and the unknown, that Edwin Klebs was known to his contemporaries and deserves to be remembered.

special reference to its occurrence in twins by Rosanoff and Handy emphasizes the idea that the most important factor appears to be the age of the mother and the authors feel that some disease of the ovary which occurs with the advancing age of the mother is of the greatest importance in producing this condition. They point out that the condition is more frequent in boys than girls and discuss further factors such as the possibility of the spermatozoon exerting a protective influence.

One of the most pretentious and important articles concerning the nature of mental disease is by Pavlov entitled "An Attempt at Physiological Interpretation of some Neuroses and Psychoses." This article appears in the *Journal of Mental Science* for April, 1934. It can hardly be presented intelligently in brief form and the reader is referred to the article. It may be stated, however, that Pavlov found that by using his concept of the conditioned reflex he was able to work out a characteristic mental state which he called "pathological inertness", and which he felt explained some of the conditions found in mental disease particularly in the obsessional neuroses and in paranoia.

In the field of treatment there have been many articles published but few that seem of much significance. Many have to do with methods of treatments which have already been tried out to some extent but a few represent some new method. Further use of methods of prolonged narcosis have brought out little that is new. Some authors call attention to the need of psychotherapy as a part of any such plan, while there are others who feel that most of the results achieved are due to the psychotherapy rather than to the prolonged narcosis. The standards for determining cure or improvement are so difficult to establish in psychiatry and the lack of control material is so common that most articles on the subject of treatment are largely impressionistic. This is particularly true concerning the manic depressive psychoses where the patients ordinarily recover if no treatment at all is given. When one reads therefore, of 37.7 per cent of cases of manic depressive psychoses recovering under prolonged narcosis treatment, there seems little value to such figures.

One interesting result of the increased frequency of encephalograms is the report from several sources of total improvement in certain cases as a result of the injection of air where certain cases of head trauma appear to have been relieved of headache, dizziness, and even convulsive attacks. Further study along this line seems indicated and it may be that some important therapeutic results can be achieved by such a method of treatment or by some modification of such treatment.

In recent years the concept of suboxidation of the brain as a cause of dementia praecox has attracted considerable attention. Mott held

strongly to this view and it is now generally accepted that there is a tendency toward a low basal metabolism in dementia praecox. At the New York Psychiatric Institute an attempt was made to treat five cases of dementia praecox by keeping them continuously for two and a half months in an oxygen chamber of approximately fifty per cent oxygen. During this period the patients were also given further treatment with carbon dioxide and oxygen. Psychotherapy was also a part of the treatment. Three control groups were used, one group receiving the continuous oxygen treatment and the combined carbon dioxide side treatment, but no psychotherapy. A second group simply lived in the fifty per cent oxygen atmosphere. A third group lived outside the oxygen chamber but received the daily treatments of carbon dioxide and oxygen. From the standpoint of therapy there seemed little value to the oxygen treatment. The cases that received psychotherapy as well did best.

Various other chemical treatments have been attempted and treatment has been carried out by injections of placental blood, of sulphur and gold, of insulin, and of manganese, also various endocrine preparations and extracts of nervous tissue have been used. The results obtained do not point to any important new method of therapy.

In the treatment of depressions hematinophyllin has apparently had some value and it is probable that within the next few years there will be further experiments with this drug. There also has been further use of ovarian extract in the treatment of involutional melancholia with some rather optimistic reports.

There has been further use of fever therapy in the treatment of general paresis and it now seems firmly established that by the use of fever therapy, particularly malaria, complete remissions may be obtained in as high as one third of all cases treated and improvement in another third. Besides malaria a large number of other methods have been used to produce hyperpyrexia. Diathermy continues to be used although the danger of burns is a serious drawback. The injection of substances, such as typhoid vaccine, the use of the electric blanket and the hot water bath, all seem to be possible methods which are somewhat simpler. Still more recently an air conditioned cabinet has been used. It is still too early to determine the advantages or disadvantages from it.

There has also been some excellent work in treating hyperthyroid children with thyroid preparations and following the intellectual development of the child by very careful psychological tests. These tests appear to demonstrate the value of thyroid treatment and indicate that the earlier a condition is recognized and treatment instituted, the greater will be the intellectual development.

group even went so far as to hold that no formal teaching of the psychoses should be given

The other point of view was that since over half of the hospital beds in this country were filled with cases of mental disease, anyone going into the practice of medicine needed some acquaintance with these serious mental disorders. It was pointed out that mental disorders are most commonly seen first by the general practitioner and that he therefore needs to have some knowledge of this subject. Furthermore, it was held that the general public turned to the physician for understanding and advice on the problem of mental disease, and if the physician who was graduated from a Class A medical school has no more knowledge than the laity as to the problems of mental disease, it would cause the lay individual to lose faith in the physician and to turn more to unqualified practitioners in the field of mental disease.

In line with this a report was submitted by Dr Franklin G. Ebaugh, entitled "Ideal Standards for the Teaching of Psychiatry in Class A Medical Schools" which was endorsed both by the Advisory Committee on Psychiatric Education of the National Committee for Mental Hygiene and by the Committee on Psychiatric Education of The American Psychiatric Association. It was held that psychiatry should be one of the fundamentals of the basic training of every physician and wherever possible, instruction should be given during all four years. The ideal type of curriculum was held to consist of

Sixteen hours of "pre-clinical instruction in psycho-biology during the first year"

Sixteen hours of "psycho-pathology and methods of study and formulation" in the second year

Sixty hours of "clinical instruction, didactic work clinics, and clerkships" in the third year

Sixty hours of "out patient work, inter-departmental consultation participation and examination of individual cases" during the fourth year

On June 21, 1934 Yale University conferred the honorary degree of Doctor of Science on Dr Adolf Meyer as an expression of the great pioneer work which he has done in American Psychiatry.

The second series of the Thomas William Salmon Memorial Lectures was given by Dr C. Macfie Campbell at the New York Academy of Medicine on April 13, 20 and 27, 1934, his subject was "Trends in Psychiatry." These lectures are to be published by the Thomas William Salmon Memorial.

In June, 1934 Dr James V. May resigned as Commissioner of Mental Diseases in Massachusetts and resumed his former position as Superintendent of the Boston State Hospital. Dr May had agreed to accept the Commissionership for a period of one year following the death of Dr Kline, but had insisted that he should be

free to return to his former position at the end of that period. Dr Winfred Overholser who had for many years been Assistant Commissioner was appointed Commissioner of Mental Diseases by Governor Ely.

The Rockefeller Foundation made a substantial gift for the increase of work in psychiatry at the Harvard Medical School. The bulk of this fund was given for the establishment and maintenance of a psychiatric unit at the Massachusetts General Hospital to be under the direction of Dr Stanley Cobb and part to establish some new work at the Boston State Hospital.

It cannot be said that any new or startling discoveries have been brought forth in the field of psychiatry during the past year. The literature has continued to be quite extensive and prolific and all varieties of topics have been dealt with.

In the field of heredity, further studies of the factors in dementia praecox and manic depressive psychoses made by Pollack and his associates in New York State and published in the Psychiatric Quarterly indicate the importance of the hereditary factor in both of these diseases.

Two recent articles by E. Bleuler of Zurich defend the idea that certain acquired mental characteristics can be inherited. This is, of course, contrary to the viewpoint of most biologists, but coming from the pen of such a distinguished physician the articles merit serious consideration. It is perhaps worth calling attention to the fact that many prominent men in the field of psychiatry, particularly a number in the psychoanalytic field, have insisted on an inheritance of acquired mental characteristics.

There has also been further work concerning the inheritance of feeble-mindedness which also confirms the hereditary nature of this condition where injury and disease have been ruled out as etiological factors. One of these articles suggests that feeble-mindedness may be transmitted as a recessive trait.

Various attempts have been made to work out causative factors in mental disease particularly in schizophrenia. Most of these studies have led to negative conclusions. Thus Freeman and Looney at the Worcester State Hospital attempted to determine whether a toxin was present in the blood or urine of schizophrenic patients. The question of toxicity was determined by noting the effect of dilutions of blood and urine of the patients on the growth of *Lupinus Albus*. The results were negative and showed no evidence of any such toxin.

Rosanoff and Inman-Kane after a study of premature birth and underweight at birth conclude that children born prematurely and underweight are much more likely to sustain cerebral injury at birth and hence this condition is a factor in the production of mental deficiency.

A study of the etiology of Mongolism with

special reference to its occurrence in twins by Rosanoff and Handy emphasizes the idea that the most important factor appears to be the age of the mother and the authors feel that some disease of the ovary which occurs with the advancing age of the mother is of the greatest importance in producing this condition. They point out that the condition is more frequent in boys than girls and discuss further factors such as the possibility of the spermatozoon exerting a protective influence.

One of the most pretentious and important articles concerning the nature of mental disease is by Pavlov entitled "An Attempt at Physiological Interpretation of some Neuroses and Psychoses." This article appears in the *Journal of Mental Science* for April, 1934. It can hardly be presented intelligently in brief form and the reader is referred to the article. It may be stated, however, that Pavlov found that by using his concept of the conditioned reflex he was able to work out a characteristic mental state which he called "pathological incoherence" and which he felt explained some of the conditions found in mental disease particularly in the obsessional neuroses and in paranoia.

In the field of treatment there have been many articles published but few that seem of much significance. Many have to do with methods of treatments which have already been tried out to some extent but a few represent some new method. Further use of methods of prolonged narcosis have brought out little that is new. Some authors call attention to the need of psychotherapy as a part of any such plan, while there are others who feel that most of the results achieved are due to the psychotherapy rather than to the prolonged narcosis. The standards for determining cure or improvement are so difficult to establish in psychiatry and the lack of control material is so common that most articles on the subject of treatment are largely impressionistic. This is particularly true concerning the manic depressive psychoses where the patients ordinarily recover if no treatment at all is given. When one reads, therefore, of 87.7 per cent of cases of manic depressive psychoses recovering under prolonged narcosis treatment, there seems little value to such figures.

One interesting result of the increased frequency of encephalograms is the report from several sources of total improvement in certain cases as a result of the injection of air, where certain cases of head trauma appear to have been relieved of headache, dizziness, and even convulsive attacks. Further study along this line seems indicated and it may be that some important therapeutic results can be achieved by such a method of treatment or by some modification of such treatment.

In recent years the concept of suboxidation of the brain as a cause of dementia praecox has attracted considerable attention. Mott held

strongly to this view and it is now generally accepted that there is a tendency toward a low basal metabolism in dementia praecox. At the New York Psychiatric Institute an attempt was made to treat five cases of dementia praecox by keeping them continuously for two and a half months in an oxygen chamber of approximately fifty per cent oxygen. During this period the patients were also given further treatment with carbon dioxide and oxygen. Psychotherapy was also a part of the treatment. Three control groups were used, one group receiving the continuous oxygen treatment and the combined carbon dioxide side treatment, but no psychotherapy. A second group simply lived in the fifty per cent oxygen atmosphere. A third group lived outside the oxygen chamber but received the daily treatments of carbon dioxide and oxygen. From the standpoint of therapy there seemed little value to the oxygen treatment. The cases that received psychotherapy as well did best.

Various other chemical treatments have been attempted and treatment has been carried out by injections of placental blood, of sulphur and gold, of insulin, and of manganese, also various endocrine preparations and extracts of nervous tissue have been used. The results obtained do not point to any important new method of therapy.

In the treatment of depressions hematoporphyrin has apparently had some value and it is probable that within the next few years there will be further experiments with this drug. There also has been further use of ovarian extract in the treatment of involuntary melancholia with some rather optimistic reports.

There has been further use of fever therapy in the treatment of general paresis and it now seems firmly established that by the use of fever therapy, particularly malaria, complete remissions may be obtained in as high as one third of all cases treated and improvement in another third. Besides malaria a large number of other methods have been used to produce hyperpyrexia. Diathermy continues to be used although the danger of burns is a serious drawback. The injection of substances such as typhoid vaccine, the use of the electric blanket, and the hot water bath, all seem to be possible methods which are somewhat simpler. Still more recently an air-conditioned cabinet has been used. It is still too early to determine the advantages or disadvantages from it.

There has also been some excellent work in treating hyperthyroid children with thyroid preparations and following the intellectual development of the child by very careful psychological tests. These tests appear to demonstrate the value of thyroid treatment and indicate that the earlier a condition is recognized and treatment instituted the greater will be the intellectual development.

An interesting study on blood sugar in relation to emotional reactions by Whitehorn confirms the findings of previous writers that there is little relation between the fasting blood sugar and the emotional state of the psychotic patient. The vast majority of such patients, even in states of extreme excitement, show a normal blood sugar. Where hyperglycemia occurred it was usually in some organic type of case or in women at about the involutional period of life.

An excellent article by Paul Schilder appears in *The American Journal of Psychiatry* for July, 1934. The article entitled "Psychic Disturbances After Head Injuries" does not lend itself to a brief summary and is a discussion of the various types of mental symptoms occurring after brain injury.

The great increase in the smoking of marijuana cigarettes has led to several studies of this subject. The habit has apparently spread from Mexico and Latin-American countries and the drug itself is the American form of hashish or Cannabis Indica. There have been many reports of the effects of smoking these cigarettes and the habit seems particularly prevalent among high school students. A certain exuberance occurs, a tendency to laugh easily, oftentimes an alteration in the sense of time and space, and repressions, particularly sexual, are removed. There is no tendency to habit formation as in opium or cocaine. The drug is little used by criminals who commonly prefer opium or cocaine. A very excellent summary of the subject, entitled "Marijuana Intoxication, A Clinical Study of Cannabis Sativa Intoxication" by Bromberg appears in *The American Journal of Psychiatry* for September, 1934.

AN ADVERTISED HEALTH CLINIC

A pamphlet has been circulated in which appears an advertisement of a Health Clinic in Boston with a doctor and dentist in attendance.

The doctor's name does not appear in the Directory of the American Medical Association so far as we have discovered, and the Massachusetts State Board of Registration in Medicine also reports that this doctor's name does not appear in the list of registered physicians. The advertisement sets forth that complete physical examination will be made for \$1.00.

Perhaps this may be a plan for emulating the practice of the Canadian doctor who charged \$1.00 per treatment and has been reported to be making a financial success of manipulation of the feet of his patients.

Whether this venture will be a financial success is doubtful, because the public is growing wary of advertised medical service although there is a gen-

A number of books have appeared which are of considerable interest to the psychiatrist and mention may be made of a few which could probably be of value to the general medical profession.

Elton Mayo has written on "The Human Problems of an Industrial Civilization" in a manner which should interest everyone.

Huddleson's "Accidents, Neuroses and Compensation" gives an excellent summary of our present knowledge of this troublesome condition.

Weyhoefer's "Insanity as a Defense in Criminal Law" has attracted considerable attention and has been generally accepted as one of the best books on this subject.

Nathan G. Goodman has written a book on "Benjamin Rush, Physician and Citizen" which should interest every follower of medicine. The discussion of Rush's service during the Revolutionary War, his criticisms, and quarrel with General Washington, and his ideas concerning mental disease all afford interesting reading.

Campbell's "Human Personality and the Environment" which represents the substance of six lectures given at the Lowell Institute is a book with which all students of personality should become familiar.

Stefan Zweig's "Mental Healers—Franz Anton Mesmer, Mary Baker Eddy, Sigmund Freud" is a very readable account of these three individuals.

The last volume of *The Association for Research in Nervous and Mental Disease*, entitled "The Biology of the Individual" is also a study of personality which will remain for some time as an important contribution to this subject.

eral impression that adequate advertising of most anything will bring favorable returns.

If it is found, on further investigation that this doctor is not registered, there will be more doubt of his competing successfully with other practitioners in Boston. There seem to be some obstacles in the way of this clinic.

THE FLOATING CONGRESS

About three hundred physicians from the United States, some with their wives, sailed on the Queen of Bermuda for Rio de Janeiro June 30, as participants in the Floating Congress.

The medical activities will be divided into seventeen sections of medical discussions. The Brazilian medical profession has arranged scientific sessions at Rio de Janeiro and Sao Paulo with special exhibits at the Oswaldo Cruz Institute of Tropical Medicine and at the Sao Paulo University with its Institute Sero-Therapeutic.

potents would all be benefited by vitamin B by mouth. This patient, then, possibly suggested pernicious anemia and he was treated with highly purified liver extract which produced no apparent results. This was evidently not a potent material because two weeks after admission treatment with liver that was potent was followed by excellent response. There was marked improvement in strength and appetite, almost complete disappearance of the soreness of the tongue, the red count rose to two million with twenty six per cent reticulocytes that is about two hundred and sixty thousand reticulocytes which is a maximal response. We see later that his red count rose to four million. In other words, he had an anemia which gave the specific response to liver as shown by maximal reticulocyte response for the red cell level and the problem is simply whether he had two diseases or whether this pernicious like anemia was secondary to his underlying disease. It is rather ridiculous for one to try to decide because there is, I think, no solution of the problem. I doubt if Dr. Mallory can tell us. However the description of the patient does not suggest a typical idiopathic pernicious anemia.

Could radiation so affect gastric activity as to produce pernicious anemia? I do not think I have ever seen it as a result of radiation alone. I wonder what Dr. Holmes will say. It may be that his diet had been grossly wrong but there is nothing in the history to suggest that. Finally he may have infiltration of the stomach with tumor tissue, with diminishing gastric activity with resulting pernicious anemia due to the lack of an intrinsic factor. It seems futile to speculate about this.

When we have a patient with marked headache and a probable leukemia or gland tumor such as this it is wise to think of some central nervous system involvement and it may even include a real leukemic meningitis. I got caught that way once, not paying enough attention to the headache. I will speak of that in a moment.

The problem in this last admission is why he had headaches and blurring vision and what actually caused death. The blurring of vision may be due to retinal hemorrhages as a result of anemia. There is no note of hemorrhages elsewhere. The hemorrhage is noted as subconjunctival and therefore I think it is fair to assume that it was due to increased intracranial pressure. I am going to guess that he had not a discrete involvement in the brain but a diffuse involvement around the meningeal vessels with this tumor and that he had what may really be called a leukemic meningitis. There is no detailed account of the death, and it is not important in this case. I assume we can take it that he did have a terminal pneumonia in addition to everything else. I should say, then that

he had clinically a leukemia which pathologically might be described as lymphoblastoma of some type, that he had an involvement of the meningeal vessels amounting to a leukemic meningitis, and that he had a symptomatic or secondary pernicious anemia.

CLINICAL DISCUSSION

DR. BERNARD M. JACOBSON. I took care of this patient during his second admission while he was in Ward 4 and we had all the data about his having been discharged on a previous admission with a biopsy diagnosis of lymphosarcoma. While he was attending the Tumor Clinic for continued x-ray treatment Dr. Chapman noticed the appearance of other symptoms, weakness, dyspnea, sore tongue and the onset of paresthesia in the hands. Dr. Chapman knowing that I was interested in pernicious anemia, got me to see him at the time of his second admission. The physical examination, the history and the blood findings could not be distinguished from that of idiopathic pernicious anemia. It is interesting in retrospect that he did have at least two high color indexes at the time of previous admission but not nearly so high at the time of the second admission.

After his discharge from Ward 4 I followed him in part during the next four months. I did not give him any parenteral liver treatment because he seemed to do very well on whole liver and domestic liver by mouth. About two months after discharge at a time when the red blood cell count was well over four million he came in with a story that was typical of acute gout involving one metatarsal phalangeal joint. He had never had any arthritic symptoms in his life before and no family history of gout. A few weeks later he came in with another story of an attack of acute metatarsal phalangeal inflammation. I saw him after the second attack when the joint was subsiding. He had very slight edema and slight brownish discoloration of the skin. I did not modify the diet in any way and sent him to the house for the third admission.

A PHYSICIAN. I should like to ask one question. Must we make a diagnosis of idiopathic pernicious anemia on the basis of a maximal reticulocyte response to treatment? I have been asked that a number of times and I am not sure whether the therapeutic test is a final test of idiopathic pernicious anemia. I should like to hear a comment on that.

DR. FRANCIS T. HUNTER. I should like to ask Dr. Jacobson whether the cell volume was high.

DR. JACOBSON. The volume index was as high as you will ever find it, around 1.6. It is far higher than we see it in the myeloid leukemias or lymphoblastomas, which rarely run over

of the red blood cells. The platelets were normal. There was an occasional reticulocyte. A gastric analysis showed no free hydrochloric acid even after ergamin. The icteric index was 8.

He was first treated with a highly purified liver extract which produced no apparent response. Two weeks after admission intensive parenteral liver treatment was started following which there was an excellent response. There was marked improvement in strength and appetite and almost complete disappearance of the soreness of his tongue. His red blood cell count was 2,070,000, with 26 per cent reticulocytes. About one month after entry he received x-ray treatment over both upper cervical and preauricular regions. The glands became swollen and somewhat softer following this treatment. He was discharged improved during the sixth week and was told to continue with the liver treatment.

Third Admission, four months later

During the interval he was seen in the x-ray clinic. His red cell count had remained around 4,000,000. A few weeks before this entry he developed headaches and blurring of vision. Several of the glands reappeared. On the day before admission, after an x-ray treatment over the skull to include the eyes because of the enlarged glands above each orbit, he became very weak and developed a severe headache. His vision failed.

On physical examination prominent subconjunctival hemorrhages were found. There were soft indefinite masses over each orbit. The liver and spleen were enlarged to percussion but were not felt. The glands in the neck, groin, elbow, axillae and back of skull were enlarged to one centimeter in diameter.

Examination of the blood showed a red cell count of 3,270,000, with a hemoglobin of 60 per cent. The white cell count was 5,200, 57 per cent polymorphonuclears and 10 per cent immature forms.

Liver by mouth and liver extract intramuscularly were given. He was given another course of x-ray treatment but he developed signs of collapse and pneumonia and died six weeks after admission.

DIFFERENTIAL DIAGNOSIS

DR WYMAN RICHARDSON: I hate to see a patient with swelling of the neck due to glands because I am always wrong in making a diagnosis of the cause of the swelling, at least until biopsy reports are available. Fortunately in this case they are available.

We have a history of enlarged glands and the only thing that seems to me to be important is that he has had drenching night sweats. I feel that that is rather against the diagnosis of metastatic carcinoma and more in favor of some lymphoid tumor. As to the intravenous

treatment, I am not sure what was in mind there.

Physical examination then is not interesting except for the glands. I think slightly irregular pupils in a man of seventy-seven are of no significance.

The red blood cell counts on the sixth and fourteenth days were 2,550,000 and 2,280,000, that is rather strange in the absence of a story of hemorrhage. I think that the first count of four million probably was an error.

The blood is interesting in comparison with the next episode. The color index according to the Tallqvist scale is high and the red counts are lower than one would expect in view of the history. There is no description of the smear. The differential count shows a slight but absolute lymphocytosis, and there are some immature cells interpreted as lymphocytes. Taken in connection with the glandular enlargement that blood smear would suggest a lymphoid tumor of a cellular type and certainly I think would justify a diagnosis of aleukemic leukemia, taken also in connection with the severe anemia. The blood picture is not that of a Hodgkin's disease, where, having gone this length of time, one would expect to find the lymphocytes reduced instead of increased.

The skin lesion may of course have been due to lymphoid involvement of the skin but there is no more mention of it and we might as well leave it as it is.

The history and physical examination on the second admission are essentially the same as previously except for sore tongue and the weakness and so on, presumably due to anemia of some sort. The scanty hair I think one can dismiss because he was known to have had considerable radiation in these regions.

We again have a very severe anemia which shows this time a relative lymphocytosis, but there is no actual increase of lymphocytes. There are less immature cells this time, not classified. The picture might be consistent with the anemia of aleukemic leukemia. In this condition we frequently get an anemia which shows marked variation in the size of the red cells, sometimes a true macrocytic hyperchromic anemia, one very difficult to distinguish from pernicious anemia. The test that has been used frequently is a therapeutic one, with the use of liver. It is rare in this type of anemia associated with leukemia to get variation in the shape of the red cells. On the other hand this patient had a sore tongue, suggesting vitamin B deficiency. It impresses me when I go around and look at patients with long-continued chronic disease, especially when I look at their tongues, that there frequently is evidence of vitamin B deficiency with or without anemia. I refer especially to patients with diseases such as ulcerative colitis or long-drawn-out gastrointestinal malignancy or patients with difficulty in swallowing or with long chronic illnesses. These

and left nothing behind? How do you feel about it Dr Holmes?

DR. GEORGE W. HOLMES I cannot definitely answer the question. Of course we do get anemias as an end result in these cases of leukemia that have been treated for a long time. Then there are cases of polycythemia which respond very readily to small doses of x ray showing that irradiation does affect the bone marrow. The question may well be raised but it cannot be answered at present.

Dr Richardson raised a question that is worth commenting upon, the question of a change in the stomach causing the anemia. We should have had an x ray examination of the stomach. We are inclined to neglect these studies in patients who have been with us for a long time.

DR. MALLORY The stomach was entirely negative at autopsy. It was a perfectly logical thing to think of, of course.

A PHYSICIAN Was the head examined?

DR. MALLORY No.

DR. HOLMES I should like also to comment on the reaction following the treatment to the head. It is quite common in radiation over the brain to have such a reaction and it is possible that the treatment did increase the intracranial pressure but in this case the situation was desperate and something had to be done.

DR. MALLORY Dr Weiss has recently been collecting cases of leukemia, and finds that central nervous system involvement is more common than not, strikingly more frequent than is generally supposed.

A PHYSICIAN Were there many specimens of bone marrow examined, Dr Mallory?

DR. MALLORY The sternum and vertebrae.

A PHYSICIAN I wonder how he could have such a generalized aplastic anemia and maintain such a respectable blood picture.

DR. MALLORY He was in five weeks and the last red count was taken a number of weeks before his death.

A PHYSICIAN Did he maintain as high a blood count as that at the end?

DR. MALLORY I cannot answer that.

A PHYSICIAN Did they make a diagnosis of leukemia?

DR. MALLORY No.

A PHYSICIAN Do you think he has lymphosarcoma?

DR. MALLORY I am inclined to think he had leukemia, but there is no positive evidence of it from the autopsy. I am inclined to think he had true pernicious anemia. What do you think, Dr Jacobson?

DR. JACOBSON At the end of the second admission the red blood cell count had gone up to three million and the glands began to recede. On Dr Hunter's advice we gave him more treatment.

I should like to ask Dr Mallory if he can distinguish the stomach in pernicious anemia from a normal one?

DR. MALLORY The autopsy was done ten hours postmortem and it would be quite impossible.

DR. JACOBSON We have one method that we have developed in this hospital for the estimation of the hematopoietic potency of various materials and various organs. We have found in one individual, a person dying of some other diseases with no anemia during life, that his liver contained 150,000 guinea pig units of activity per 100 grams of liver. We have assayed the livers of two patients dying of pernicious anemia in relapse and in both these instances there were less than 500 units of activity per 100 grams of liver. In this particular patient who died in what we might call partial remission, the content was 47,000 and these figures all agree with the results of human assays of such livers in three other investigations, namely that the normal liver is about as good as hog or beef liver, the pernicious anemia in relapse liver is practically devoid of activity and the pernicious anemia in remission liver is active but not nearly so active as the normal human liver. So we have some functional evidence that he had pernicious anemia.

CASE 21282

PRESENTATION OF CASE

A fifty two year old Irish laborer entered complaining of abdominal pain of three days' duration. (An accurate history could not be obtained because of the condition of the patient.)

Three days before entry, early in the afternoon the patient developed generalized lower abdominal pain. This pain was his chief symptom and was severe enough to keep him awake at night. He had lost his appetite but had not vomited. His bowels had not moved during the past two days. He had been followed by a physician who had given him an enema the day before entry. There was no previous history of abdominal pain. He denied ever having been sick before.

Physical examination showed a very acutely ill man with a very foul breath. His tongue was dry. The heart and lungs were negative. The blood pressure was 100/60. His abdomen was very stiff and uniformly tender, not more on one side than the other. Rectal examination was negative. The reflexes were normal.

The temperature was 101.6°, the pulse 140. The respirations were 34.

No urine could be obtained on admission. The blood showed a white cell count of 34,000.

An abdominal x ray film showed no free air beneath the diaphragms. No fluid levels were seen in the unusual gas shadows of the abdomen.

About 4 liters of 5 per cent glucose was administered intravenously. Another attempt to

13 I think it is the experience of most people that the effect of liver extract in large doses in the non-pernicious anemia, macrocytic anemias—if any effect at all is noticed—is a very irregular one, and I doubt whether anybody has observed a true reticulocyte crisis with a specific gain of red cells and improvement of symptoms in any disease other than something like pernicious anemia. I have one functional test regarding this diagnosis that I will mention later.

DR ARLIE V BOCK Dr Richardson's diagnosis of leukemia seems to me to be almost impossible in view of the response to liver and the great regeneration of red cells. We look upon leukemia as a widespread bone marrow tumor involvement with destruction of normal blood forming machinery and if it is a leukemia I should think it would be most unusual to get this response. I think he has two independent diseases.

CLINICAL DIAGNOSES

Lymphosarcoma
Pernicious anemia?

DR WYMAN RICHARDSON'S DIAGNOSES

Acute leukemia (lymphoblastoma)
Leukemic meningitis
Symptomatic (secondary) pernicious anemia

ANATOMIC DIAGNOSES

Lymphoblastoma, ? giant follicular type, with involvement of the spleen, kidney, bone marrow and lymph glands
Bronchopneumonia
Septicemia, staphylococcus aureus
Hydrothorax, bilateral
Pulmonary edema
Pulmonary atelectasis
Pleuritis, chronic fibrous, left
Arteriosclerosis, marked coronary, moderate aortic
(Gout)
Prostatic hyperplasia

PATHOLOGIC DISCUSSION

DR TRACY B MALLORY There is one prognosis which Dr Richardson made which is absolutely correct and the safest he could have made, that is that the pathologist would not be able to make a diagnosis. The one thing that most of us expected to find in this patient was a marrow full of cells whatever they might be, if he had pernicious anemia, megaloblasts, if leukemia, lymphoblasts or some form of lymphocyte. The rather surprising result of the autopsy was a completely aplastic bone marrow. I think you can see pretty readily with this low power that the fat cells have been almost entirely replaced but that the actual marrow cells are very few and far between. What makes up the great majority of the marrow is

a sort of gelatinous, edematous fibrous tissue, only here and there can you see a few small collections of marrow cells. I suppose the number of marrow cells is reduced to one-fiftieth or one-hundredth of the normal amount. In other words a very severe grade of aplasia or atrophy of the bone marrow is present.

The diagnosis of lymphoma had been made a few years ago and at that time it was considered to be of the sarcomatous type. On reexamination it is evident that the original diagnosis as to type is wrong, it should have been called giant follicular lymphoma rather than lymphosarcoma. That is a diagnosis with which many of you are probably still relatively unfamiliar. It is only within the last five years that we have been recognizing them. I have no doubt that, if we were to go back over our entire lymphoma material, we would pick up a great many cases that have been classed under other diagnoses.

Follicular lymphomas may logically be considered so nearly the reproduction of normal lymphoid tissue that true, albeit somewhat typical, follicles are found. For that reason it is easily missed and may be passed up as simple hyperplasia. In other instances the follicles are so numerous, so large, and so closely packed together that unless the specimen is carefully examined with a very low power their presence will not be recognized.

The general principle that well differentiated tumors are of low malignancy in comparison with poorly differentiated ones seems to hold for these neoplasms. Ewing goes so far as to regard some of them as benign, our own experience is that they always recur though the interval, as in this case, is apt to be a long one. Five to ten years of good health between primary tumor and death is by no means uncommon. In the recurrences the growth is not so typical and the differentiation is much poorer. That was the case here. Lymph nodes, spleen and kidney were extensively involved but only the kidney showed characteristic follicles.

The puzzle of the case lies in the bone marrow. Did the patient at one time have leukemic infiltration of his marrow so extensive as to displace all the normal cells? I feel that is a possibility since I have seen another case of leukemia—proved by bone marrow biopsy—come to autopsy with a totally aplastic marrow. Did he ever have pernicious anemia? The autopsy gives us no clue. Did he develop a primary aplastic anemia or a secondary one due to excessive x-ray or to Fowler's solution? Those possibilities certainly cannot be ruled out. My personal preference, however, lies with the hypothesis of leukemia. I should like to hear Dr Holmes' opinion. Could x-ray treatment produce this result in a normal marrow or in pernicious anemia, or do we have to assume that there was a lymphomatous involvement of the bone marrow first and the x-ray destroyed that

and left nothing behind? How do you feel about it, Dr. Holmes?

DR. GEORGE W. HOLMES. I cannot definitely answer the question. Of course we do get anemias as an end result in these cases of leukemia that have been treated for a long time. Then there are cases of polycythemia which respond very readily to small doses of x ray showing that irradiation does affect the bone marrow. The question may well be raised but it cannot be answered at present.

Dr. Richardson raised a question that is worth commenting upon, the question of a change in the stomach causing the anemia. We should have had an x ray examination of the stomach. We are inclined to neglect these studies in patients who have been with us for a long time.

Dr. MALLORY. The stomach was entirely negative at autopsy. It was a perfectly normal thing to think of, of course.

A PHYSICIAN. Was the head examined?

Dr. MALLORY. No.

Dr. HOLMES. I should like also to comment on the reaction following the treatment to the head. It is quite common in radiation over the brain to have such a reaction and it is possible that the treatment did increase the intracranial pressure but in this case the situation was desperate and something had to be done.

Dr. MALLORY. Dr. Weiss has recently been collecting cases of leukemia and finds that central nervous system involvement is more common than not, strikingly more frequent than is generally supposed.

A PHYSICIAN. Were there many specimens of bone marrow examined, Dr. Mallory?

Dr. MALLORY. The sternum and vertebrae.

A PHYSICIAN. I wonder how he could have such a generalized aplastic anemia and maintain such a respectable blood picture.

Dr. MALLORY. He was in five weeks and the last red count was taken a number of weeks before his death.

A PHYSICIAN. Did he maintain as high a blood count as that at the end?

Dr. MALLORY. I cannot answer that.

A PHYSICIAN. Did they make a diagnosis of leukemia?

Dr. MALLORY. No.

A PHYSICIAN. Do you think he has lymphosarcoma?

Dr. MALLORY. I am inclined to think he had leukemia but there is no positive evidence of it from the autopsy. I am inclined to think he had true pernicious anemia. What do you think, Dr. Jacobson?

Dr. JACOBSON. At the end of the second admission the red blood cell count had gone up to three million and the glands began to recur. On Dr. Hunter's advice we gave him more treatment.

I should like to ask Dr. Mallory if he can distinguish the stomach in pernicious anemia from a normal one?

Dr. MALLORY. The autopsy was done ten hours postmortem and it would be quite impossible.

Dr. JACOBSON. We have one method that we have developed in this hospital for the estimation of the hematopoietic potency of various materials and various organs. We have found in one individual, a person dying of some other diseases with no anemia during life, that his liver contained 150,000 guinea pig units of activity per 100 grams of liver. We have assayed the livers of two patients dying of pernicious anemia in relapse and in both these instances there were less than 500 units of activity per 100 grams of liver. In this particular patient who died in what we might call partial remission, the content was 47,000 and these figures all agree with the results of human assays of such livers in three other investigations, namely, that the normal liver is about as good as hog or beef liver, the pernicious anemia in relapse liver is practically devoid of activity and the pernicious anemia in remission liver is active but not nearly so active as the normal human liver. So we have some functional evidence that he had pernicious anemia.

CASE 21282

PRESENTATION OF CASE

A fifty-two year old Irish laborer entered complaining of abdominal pain of three days' duration. (An accurate history could not be obtained because of the condition of the patient.)

Three days before entry, early in the afternoon the patient developed generalized lower abdominal pain. This pain was his chief symptom and was severe enough to keep him awake at night. He had lost his appetite but had not vomited. His bowels had not moved during the past two days. He had been followed by a physician who had given him an enema the day before entry. There was no previous history of abdominal pain. He denied ever having been sick before.

Physical examination showed a very acutely ill man with a very foul breath. His tongue was dry. The heart and lungs were negative. The blood pressure was 100/60. His abdomen was very stiff and uniformly tender not more on one side than the other. Rectal examination was negative. The reflexes were normal.

The temperature was 101.6°, the pulse 140. The respirations were 34.

No urine could be obtained on admission. The blood showed a white cell count of 34,000.

An abdominal x ray film showed no free air beneath the diaphragms. No fluid levels were seen in the unusual gas shadows of the abdomen.

About 4 liters of 5 per cent glucose was administered intravenously. Another attempt to

procure a urine specimen by catheterization three hours after the intravenous was unsuccessful. Only a few drops of mucus but no urine was obtained. He rapidly went downhill, became comatose and died approximately twelve hours after admission without having regained consciousness.

DIFFERENTIAL DIAGNOSIS

DR LELAND S. MCKITTRICK: The positive findings as I see them are severe generalized pain of three days' duration, and no nausea or vomiting in a man who had never been sick before, and whose bowels had not moved for two days. In addition to that we have an acutely ill patient with distress, dry tongue, blood pressure 100/60, which I assume to be the result of his collapse rather than a normal blood pressure, and who has the physical signs of peritonitis. He has passed no urine since his admission to the hospital.

The inability to get urine, and I presume we can assume that the catheter went into the bladder all right, might be due to one of three things: obstruction at the base of the bladder, so that no urine could get into the bladder, frank rupture of the bladder, or failure of the kidneys to excrete it. It is perfectly possible that it might be due to the fact that the kidneys were not excreting urine during the period between the last voiding and the time he was catheterized. I do not think we have anything here to make us assume that he had an obstructing lesion shutting off his ureters. One might say that he had a ruptured bladder with resulting peritonitis. I believe that if you catheterized such a bladder and there was no urine in it there would be blood in what was obtained. Therefore, I believe the inability to get urine was probably due to the fact that urine was not being excreted during the particular time between his last voiding and catheterization. If that is the case it might possibly be secondary to the terminal stages of an abdominal condition. There again without any more lead than we have in the history or physical examination one cannot do much more than speculate as to the cause of peritonitis which I also assume is present.

One may have a peritonitis of the chemical type such as occurs in acute pancreatitis from the bile and blood-tinged fluid, or it might have an infectious origin. I do not believe there is any reason for assuming it to be a chemical peritonitis. I do not believe he has acute pancreatitis because he is not distended, is not vomiting and has not the tenderness along the pancreas that usually occurs with pancreatitis. I do not believe it is blood in the peritoneal cavity because I cannot quite fit together an intelligent story which would give such a picture. If it is a septic peritonitis one might get it

either from perforation of an organ or from gangrene.

This is a rather unusual story for appendicitis with perforation and death. It is possible of course. It is the most common cause but where your cases are selected you cannot very well go on the law of chances. A ruptured diverticulum of the sigmoid or a perforated peptic ulcer might give the same picture. I am interested in the unusual gas shadows.

DR GEORGE W. HOLMES: There is not much to see in this film. It was taken probably with the patient lying on the back and might miss free air in the abdominal cavity. He evidently had a tube in the stomach. The shadow that you see on the left side is probably gas in some part of the gastrointestinal tract. We would not think it was particularly unusual. They do not say what was obtained with the stomach tube.

DR HENRY H. FAXON: Nothing of any great significance.

DR HOLMES: They do not say what results the physician got from the enema.

DR FAXON: The bowels had not moved for two days.

DR MCKITTRICK: That does not help very much. The onset certainly is not typical of a perforated ulcer.

DR FAXON: As I remember the story the present illness was more than three days. He had discomfort in the lower abdomen five days before and felt that the best thing to do was to take something for it. Accordingly he took a sufficiently substantial amount of liquor to become unconscious of pain and kept himself in that state for three days. When he became conscious he found the pain still there and again "loaded up" and carried on until the day of entry, when he was no longer strong enough to go out for any more, so his friends brought him a half pint of straight whiskey. That was one reason we could not get a better story. I think he had more pain than he complained of.

DR ROBERT G. GLENDY: Upon further investigation of the case after death I learned from the doctor who took care of him outside and who saw him three days before he came in here, that the pain was chiefly in the upper abdomen and that he had considerable precordial pain with some nausea and vomiting.

DR MCKITTRICK: I think we had better stop. It is getting more complicated. I still do not think that he had perforated ulcer. I cannot exclude it. I cannot exclude anything. I can only rationalize a little bit and be wrong. The other thing that presents itself to me is to try to coordinate the unusual complete anuria with the abdominal findings. With a pretty good cardiovascular system and good kidneys, this man could not have been as well so he said, never having been sick before, and have a com-

plete shutdown of the kidneys, without some very dramatic accident. He had a 34 000 white count. He is tremendously dehydrated and it does not mean much but I do think that one of the causes of a very short terminal illness, with obscure general abdominal pain and widespread evidence of peritonitis is peritonitis secondary to gangrene of the bowel. A mesenteric thrombosis to me would fit the whole picture of anuria and an early death after a relatively short and obviously very serious illness. I can only say that I believe the man has no mechanical obstruction to his ureters. I believe he died with a peritonitis. I believe his anuria is secondary to the peritonitis plus another fundamental process and my first choice as to the cause of his peritonitis would be a mesenteric thrombosis.

DR. FAXON. When he came in we felt he had a peritonitis. I think that we laid less stress on the failure to get a specimen of urine by catheter than has been brought out in the present discussion. I could not explain the picture but feeling that the man had peritonitis with the most likely etiology on the law of chances a ruptured appendicitis—although it was certainly atypical for that—we brought him to the operating amphitheater. His condition at that time was so critical it was obvious that operative interference would certainly end fatally so we felt that it was wiser to carry him along with intravenous therapy and see if he would respond. Instead of responding he went steadily and rapidly downhill without operation.

CLINICAL DIAGNOSIS

Peritonitis, ? cause

DR. LELAND S. MCKITTRICK'S DIAGNOSIS

Mesenteric thrombosis with secondary peritonitis and anuria

ANATOMIC DIAGNOSES

Aneurysm of the aorta, dissecting
Hemorrhage into myocardium about right coronary artery

Central necrosis of liver
Cloudy swelling of the kidneys

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY. Obviously the data are entirely inadequate for a diagnosis on this case. At Dr. Faxon's suggestion we put in the only lead that there was and emphasized it a little bit. If we had had some of the information which Dr. Glendon has since picked up I think we could have given you a better story. What he had was a dissecting aneurysm of the aorta running all the way from the aortic ring down to the iliacs. Dissection did not extend down any of the branches of the abdominal aorta but I think it is fair to assume that they were probably functionally occluded by pressure at their mouths. The kidneys were not very remarkable grossly. Microscopically they show a diffuse cloudy swelling of the parenchyma. The most definite change and one which I think is strong evidence for circulatory insufficiency was found in the liver where the central two thirds of every lobule was completely necrotic. We have seen this lesion with particular frequency in cases of acute bleeding duodenal ulcer, so that I feel that we have good histologic evidence of insufficient circulation of the liver and suggestive though not certain histologic evidence of interference of circulation of the kidneys. I believe that is the only way in which the symptoms can be connected up. There was little or no blood circulating through the kidneys and consequently no urine was passed. The bladder and prostate were entirely negative.

LOVING DARKNESS RATHER THAN LIGHT

THE resolution asking for the appointment of a commission to study the condition of medical education in Massachusetts, which has been before a committee of the legislature for several weeks has, we understand, not met the approval of influential members of the Legislature. A full setting forth of the basis for this action has not been made public but a discussion of the matters involved is pertinent at this time.

Substantially the commission was to be a fact finding body. Possible objection might be raised on the grounds that the commission was incompetent or unnecessary or expensive. The actual objections were on the grounds of expense, prejudice on the part of the commission and lack of need for the investigation as expressed at the hearing. The question of expense need not be considered if the investigation were worth anything it would be worth the fifteen hundred dollars for clerical services as the commission was to be unpaid.

The question of competence does not need lengthy discussion. The commission was to consist of fifteen members: one senator, three representatives, two physicians appointed by the Governor, the Commissioner of Education, the Commissioner of Public Health, the Chairman of the Board of Registration in Medicine, and the deans of the six schools in Massachusetts from which graduates are accepted for examination for the practice of medicine. Until the persons were named and had served, no final judgment could be passed, but the proposed list represents grounds for a reasonable expectation that the report would be intelligent and intelligible.

The chief prejudice was shown by the opponents of the resolve who claimed that the proponents were "tyrants" and that the commission was "packed" against the "small schools", and in the nature of things could not render a fair report. This general insult was gratuitous and unwarranted.

The necessity for the investigation remains to be considered. Are investigations of educational institutions necessary? When? How? By whom? Why? Certainly investigations are necessary and the reports of college and university presidents indicate the self-critical spirit, sometimes a little severe, in which many of the activities of the institutions are reviewed annually. Sometimes a spirit of complacency and self-congratulation is evident, but the possibility for self-criticism exists, and although these documents do not usually receive wide circulation except among alumni, no effort is made to conceal them.

Occasionally there is investigation of another sort, as recently of the University of Chicago by the Illinois legislature. On report of alleged improper activities, it was made promptly and no improper activities were found. Another type of investigation has been made by organizations interested in medical education, because, and it is a matter of record, medical schools were purely commercial organizations in many cases. Commercialism in professional education is intolerable, and the force of public opinion, following the light thrown by these investigations, has caused nearly all of the commercial medical schools to disappear.

It is recognized in scientific circles that a determination of facts should precede action and the beneficial and stimulating effects of knowing the facts can hardly be overestimated. So in recent months there has been undertaken again a careful study of medical education in the United States and the report is expected within the next year. The report will not include schools of medicine or osteopathy which have refused to be surveyed.

Why should a school refuse to be surveyed? Why should it refuse to make known how it car-

ries on medical education, how it provides instruction for its students, how it upholds the ideals of the medical profession?

The recent attempt in Massachusetts to discredit education suggests, perhaps that these schools which refuse and apparently fear a survey, have such high standards that their pre-eminence would subject them to jealous attack. On second thought, however, it seems more probable that they fear exposure because they fear the result of the action of public opinion against matters discreditable.

If their records are clear they ought to be the first to demand a survey so that all men may know that they have been unjustifiably suspected of selling shoddy medical education, or of sharp practice or of something worse.

PASTEURIZATION OF CERTIFIED MILK OFFICIALLY ACCEPTED

THE American Association of Medical Milk Commissions at its annual meeting in Atlantic City last month recorded two notable achievements, it elected Dr. Milton J. Rosenau as president and it unanimously accepted the pasteurization of certified milk as an official, although not an obligatory, procedure.

Dr. Rosenau, both as professor of hygiene at the Harvard Medical School and as an accepted leader in public health movements, has long been recognized as one of the uncompromising exponents of safe milk and clean milk. His election to succeed Dr. Hugh L. Dwyer, is a tribute to his leadership and a guarantee that the Association of Milk Commissions will continue to be as it has been in the past, a guiding spirit in the progressive improvement of the standards of milk production.

The fact that improvement in the production of so much of our milk supply has tended to lessen the vital importance of certified milk in certain of the uses of milk, such as infant feeding, must not cause us to lose sight of the fact that certified milk has for over forty years set a goal and served as a model in this improvement. Moreover, most of the more recent continued advances except for pasteurization, have been inaugurated by certified milk.

The certification of milk was created at a time when raw milk was considered as an asset, particularly in the feeding of infants, and the raw state was consequently considered as a sine qua non in its production. It may be that pride in the ability conscientiously to combine safety with rawness was one of the factors which delayed for so long the acceptance of pasteurization, in any event, for many years, according to the standards of the Association, certified milk could not be pasteurized milk.

In the face of this prejudicial fact it is a mat-

ter of interest and of considerable local pride that the Boston Medical Milk Commission, some four or five years ago, not only allowed but encouraged its producers to market certified pasteurized milk in defiance of the regulations of the Association, and put the stamp of its approval on the product. Some efforts were made to discipline our Commission for its revolutionary attitude but strong in its convictions it continued its independent course, and the matter was allowed to drop.

Acceptance of pasteurization was the wisest course for the Association to follow. Certified milk has a distinct place in the milk industry, and meets a distinct demand from the consumer for a milk produced as nearly ideally as possible, but without pasteurization, in this day when pasteurization is a household by word, it suffered an insuperable self-imposed handicap, except in such sections as our own where the tradition had been broken. With this handicap removed certified milk may continue to set the standard by which all good milk is produced.

The only unhappy note at the meeting this year was introduced by the resignation of Dr. Harris Monk, for a number of years the secretary and treasurer of the Association.

PREVIEW OF SCIENTIFIC PROGRAMS

SIXTY FOURTH ANNUAL MEETING
AMERICAN PUBLIC HEALTH ASSOCIATION
AND
MEETINGS OF RELATED ORGANIZATIONS
MILWAUKEE, OCTOBER 7-12, 1935

More than 2000 professional public health workers from every state in the Union, from Canada and from Mexico, will assemble in Milwaukee the week of October 7 at which time the following organizations will be in convention.

American Association of School Physicians
International Association of Dairy and Milk Inspectors
Conference of State Sanitary Engineers
International Society of Medical Officers of Health
Association of Dairy, Food and Drug Officials
Conference of Wisconsin Health Officers

From scientific programs totalling 400 presentations on subjects timely in the fields of public health, preventive medicine and sanitation, a few of the highlights are selected

Mental Hygiene has been forging ahead so steadily in interest that an entire session will be devoted to it this year for the first time

Papers on Economic Consequences of Ill Health, on Health Department Functions—preventive, nursing, medical care, dental care, hospitalization and maternity care—and the Health Department Relationships to the Activities of the Welfare Department and of the Medical Profession will make up a program on the health department and the social security program. The contributors here will be health officers, economists, practicing physicians, welfare directors and officers of government

The Fifteenth Anniversary of the Association's Committee on Administrative Practice is to be commemorated by a program in which those who have been most intimately connected with its development will review its history and accomplishments, detail the present status of its work, and cast an eye ahead upon its hopes for the future

Dr E L Bishop, President of the A P H A. and Dr Walter E Brown, President Elect, are always worth listening to, speaking as they do from a wealth of practical experience and personal philosophy

Professional Education is the subject for discussion at a luncheon meeting on Wednesday. The committee is prepared this year to make some important announcements of policies. Particularly in view of the new personnel that will certainly be drawn into public health work with the passage of the Social Security Bill, the determination of what constitutes adequate preparation for a career in public health is of paramount concern

Another luncheon session, now traditional at Annual Meetings, is the one devoted to Diphtheria Immunization

The many allied organizations and special groups that meet with the American Public Health Association

tion add interest and variety to the proceedings. Joint sessions are being arranged by various Sections with the American Association of School Physicians, the International Association of Dairy and Milk Inspectors, the Association of Food and Drug Officials, the Conference of State Sanitary Engineers, the American Association of State Registration Executives, The Association of Women in Public Health, Delta Omega, Johns Hopkins, Massachusetts Institute of Technology and Harvard Alumni, and the Conference of State Laboratory Directors will dine lunch or breakfast and confer.

The ten Section programs reflect present day attitudes and are thoroughly infiltrated with social and economic significance. The federal health program is given a large share of attention and its possibilities and implications are thoroughly covered. The following subjects will indicate the breadth and scope of Section activity:

Public Health Significance of Poisonous Substances in Foods

A Planned Milk Control for State and Nation
Standard Methods for the Examination of Shellfish

An Improved Agar for Use in Making Bacterial Counts from Milk

Proposed Changes in Standard Methods for Bacteriological Examination of Milk

Whooping Cough and Measles
Mentality and Morbidity
Pneumonia as a Community Health Problem
Child Health at Different Levels
Growth and Nutrition
Health Training and Instructions in Schools
Scarlet Fever
Animal Diseases Affecting the Public Health
Recent Progress in Biological Products
Consumer Demand for Vital Statistics
Sanitation in Rural and Recreational Areas
Air Conditioning and Industrial Health
Occupational Diseases
Present Status of the Vitamin B Complex
Food Advertising under the Food and Drug Act

Maternal and Neonatal Hygiene
Adequate Health Service for the Child
Commercial Advertising: Challenge to Health Education
Community Organization for Health Education

FERA Problems
Typhoid Carriers
Institutional Outbreaks of Pneumonia

The preliminary program will be published in full in the September issue of the American Journal of Public Health.

LIST OF GRADUATES AND HOSPITAL INTERNSHIPS OF THE HARVARD MEDICAL SCHOOL CLASS OF 1935

Name	Hospital	Service	Dates
Appleton, F. M.	Mary Hitchcock, Hanover N. H.	Rotating	Jan. '35-Jan. '37
Barrow, W.	Mass. General Boston	Surgical	July '35-Aug. '37

THE NATION'S BIRTH RATE

The report from Washington as published by the Bureau of the Census shows that there were 2,158,919 live births in this country in 1934 a rate of 17.1 per 1,000 population which is an increase over 1933 when the rate was 16.6

The three Pacific Coast States had the lowest rate. The high rates were in the Southern States and West Virginia.

The infant mortality for the whole country rose from 58.1 per 1,000 live births in 1933 to 59.9 in 1934

STATISTICS FOR NEW ENGLAND

CORRESPONDENCE

AN EARLY PLAN FOR PREPAID
HOSPITALIZATIONEditor, *New England Journal of Medicine*,

If anyone thinks that a monthly or annual payment to insure hospital care in case of need is a new and novel proposition, it may be of interest to note that on January 1, 1867 Rt Rev John J Power established in Worcester a hospital of a few beds under control of the Sisters of St Anne's Convent—"to encourage providence and maintain self respect" a trifling monthly sum was required by which one became entitled to a bed and nursing in time of sickness, or to quote from the announcement "By payment of \$3.00 any person may secure the right to a bed with doctor's care, nursing and medicine for one year"

This was the first general hospital in Worcester

Yours truly,

SAMUEL B WOODWARD, M D

58 Pearl Street. Worcester. Mass

RECENT DEATH

TURNER—MAURICE WORCESTER TURNER, M D, aged seventy eight, of Brookline, Mass, died at his home, 788 Washington Street, June 29, 1935

Dr Turner was born in Brooklyn, N Y, the son of Dr John Turner and Emma Worcester Turner. He graduated from the Boston University School of Medicine in 1889 and soon after settled in Brookline. He filled the chair of Theory and Practice of Medicine in his Alma Mater and was associated with Dr Conrad Wesselhoeft in the Department of Pathology and Practice of Medicine. He served on the staff of the Massachusetts Homeopathic Hospital and was a member of the Board of Trustees of the New England Baptist Hospital. In 1911 he was President of the International Hahnemannian Association and held membership in many homeopathic societies.

He was a Mason, Secretary of the Massachusetts Order of Founders and Patriots of America, and at his death was secretary of this body.

his second year as President at the Saas of the Revolution at Massachusetts at the time of his death.

He is survived by his widow Mrs Abby R (Corliss) Turner and a daughter Mrs Fred B Maynard, of Arlington

REPORTS OF MEETINGS

WILLIAM HARVEY SOCIETY

Dr Jonathan O Meakins president of the American College of Physicians addressed the William Harvey Society at its meeting at April twelfth at the Beth Israel Hospital His subject was Cardiology During the Past Three Hundred Years—The Legacy at William Harvey Dr Cadis Phipps presided.

Doctor Meakins briefly reviewed some of the important data in the history of medicine Michael Servetus both a theologian and a scientist at the mid sixteenth century was the first to describe the pulmonary circulation Many of his conclusions were based on direct observation and were an example of the thought and reasoning of his time He did not divorce himself from the idea of the spirits of the body which Galen had promulgated By order of Calvia he was burned at the stake because of his religious theories.

Father Paul may have been acquainted with the valves of the veins but Fabricius was the first to publish a description of them William Harvey after fourteen years of study under Fabricius was thoroughly convinced of the circulation of the blood from the right heart to the lungs and back to the heart where it was pumped into the general circulation His was the first comprehensive investigation of the circulation and his facts were collected from direct observation and experimentation He wrote a masterly discussion of this system and gave his proof for his beliefs Although the book was announced in 1616 it was not published until 1628

At this time the era of experimentation was in full swing in Great Britain Bacon was a contemporary of Harvey and insisted on experimental observation as the safe method of investigation After the publishing of Harvey's book his theories received much opposition and his practice fell off greatly

Malpighi was born in 1628 and during his lifetime carefully investigated the mysteries of the capillaries During the next century and a half numerous scientific discoveries were made and by 1650 many intellectuals had handed together for help advice and work They met weekly in London to discuss philosophical and scientific matters Among other members were Christopher Wren architect, and Robert Boyle physicist.

William Harvey's work was enthusiastically received by the following generation, and further study of the circulation and respiration was carried out Malpighi with his microscope studied the lung of dogs and demonstrated the small air sacs and their

relation to the capillaries which ran between the arteries and the veins Respiration was thoroughly investigated by several men The change in the color of the blood as it passed through the lungs was shown to be due to a substance which was absorbed in the lungs This great wave of investigation swept away much of the supposed knowledge of Galen and Hippocrates Harvey's legacy consists of the following first, the overthrow of the authority of the past secondly the introduction to the use of hypotheses proved by experimental observation and thirdly the use of man and lower animals to obtain experimental data For some time after the activity of this era men's minds sank into a sort of lethargy and it was a hundred years after Harvey before there was another important step in the description of the circulation Stephen Hales a clergyman measured the blood pressure and studied the capillaries and their power to dilate and contract He showed that brandy and certain other drugs could cause a contraction of the capillary vessels and gut, although his observations were not generally accepted for many years In the eighteenth century Lavoisier demonstrated that the act of respiration removed a part of pure air and gave off carbon dioxide He showed that nitrogen played a most active part He suggested that the name oxygen be given to this necessary constituent of air and he isolated it in pure form Over a hundred years later Haldane demonstrated the importance of carbon dioxide in the regulation of the respiration

In recent times there has been a rebirth of experimental observation in medicine Sir James MacKenzie put cardiac disease on a rational clinical basis His chief work was done before the time of x-ray and the electrocardiogram In 1896 the sphygmomanometer was introduced clinically

Doctor Meakins showed several interesting slides to demonstrate his lecture

AMERICAN MEDICAL EDITORS AND AUTHORS ASSOCIATION

Atlantic City June 15 1935

The sixty-sixth annual convention was called to order by the President, Dr Dean Lewis, who introduced the Guests of Honor

Hon Harry Bacharach Mayor of Atlantic City welcomed the membership and presented the Association with a key to the City The other Guests of Honor Hon Edward A. Kenny U S Congress Hon. Shirley Wyne M D former Commissioner of Health and Hon. S. S. Goldwater M.D., Commissioner of Hospitals New York, were next introduced.

Dr Frederick L. Patry psychiatrist of the New York State Department of Education made a plea for the family physician to increase his knowledge of psychiatry in order to handle more scientifically cases of neurosis due to family friction. Doctors A. A. Brill New York psychoanalyst, and K. Winfield Ney New York Brain Surgeon, added to Dr Patry's suggestion by citing many cases and

examples of the results following the proper use of psychiatry in such cases

Dr Shirlev Wynne told the Association that it was inevitable that a realignment would occur relative to the way medical service would be distributed in the future. At present it is a question whether there will be voluntary or compulsory insurance. State Socialized Medicine looms in the background.

The problems of the Medical Editor were handled by Dr George Lake, Editor of *Clinical Medicine*. Much enthusiasm was developed concerning his copyright plan to eliminate the throw away journals. He stated that Editors should cooperate with the efforts of the Association in their behalf.

The problems of the Medical Publishers were cleverly handled by Mr Paul Hoeber. His address gave an answer to many authors as to why contributions which they considered par excellence were not accepted for publication.

After a get-together luncheon, Dr S S Goldwater told the Association of the Hospital Problems he had to contend with. He said that the institutions needed \$10,000,000 to continue their work and added that facilities were particularly inadequate for the care of chronic and venereal patients. He said that with the majority of internes receiving but little money from home, owing to the depression and getting no salaries, they were finding it difficult to continue their training.

Dr De'n Lewis, President of the Association, addressed the Congress on "Improving the Quality of Medicine." In his address which members will long remember he touched on the subject of fee splitting—a practice he abhorred but would condone if done openly. He said that those who wanted to split fees invariably insisted on secrecy.

Dr H Lyons Hunt, Director General of the Association closed the program with a report on the financial status and informed the Convention that since Jan 1, 1935, 220 men were proposed for membership in the Association, of which number 48 had been elected.

At the close of the convention, a resolution was passed putting the Association on record as "basically and fundamentally opposed to State medicine, because it lessens the efficiency of service to the public and the dignity of the profession."

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING MONDAY, JULY 15, 1935

Wednesday, July 17—

*12 M. Clinico-Pathological Conference Children's Hospital

Thursday, July 18—

*12 M. Clinico-Pathological Conference Massachusetts General Hospital

Saturday, July 20—

*10-12 Staff rounds at the Peter Bent Brigham Hospital. Open to practicing physicians

*Open to the medical profession

*Open to Fellows of the Massachusetts Medical Society

August 29 - September 5—Latin American Congress of Physical Therapy, X-Ray and Radium. For information address Dr Madge C L McGuinness, 1211 Madison Avenue, New York City

October 7-10—American Public Health Association will meet in Milwaukee, Wisconsin. For information address the American Public Health Association, 50 West 50th Street, New York City

October 21 - November 2—1935 Graduate Fortnight of the New York Academy of Medicine. See page 898, issue of May 9

October 28 - November 1—The Twenty-Fifth Clinical Congress of the American College of Surgeons. See page 1065, issue of May 30

BOOKS RECEIVED FOR REVIEW

Report of the Committee for the Investigation of Sterilization. Boston. American Neurological Association. 132 pp

The Story of Medicine in the Middle Ages. David Riesman. 402 pp. New York. Paul B Hoeber, Inc. \$5 00

Précis de Thérapeutique et de Pharmacologie. Septième Edition. A. Richaud et R. Hazard. 1257 pp. Paris. Masson et Cie, Éditeurs. 100 fr

BOOK REVIEWS

Gynecology Brooke M Anspach Fifth Edition
With the assistance of Philip F Williams and
Lewis C Scheffoy 832 pp Philadelphia and Lon-
don J B Lippincott Company \$9 00

Here are 812 pages of lucid fluent text obviously written by a scholarly cultured gentleman. There are 769 excellent illustrations accurately informative and conveniently placed. This is especially true of the many diagrams and drawings of operative procedures. The detailed completeness of this book, with its entire lack of verbosity and irrelevancy is most impressive. In addition to gynecology there are five chapters of female urology and two of diseases of the rectum. There is an incomparable sixteen-page discussion of hachachio perhaps the commonest complaint of women. The turbulent subjects of endocrinology menstruation and sterility are presented with scrupulous conservatism. Consideration of radium and x-ray is adequate for those equipped mentally and instrumentally for their use. Of the main body of the text these portions already mentioned are perfect samples. It is a most excellent book of which the authors should be exceedingly proud—a book well worth purchase and study.

La Renaissance de la Médecine Humaine Auguste
Lumière 204 pp Lyon Imprimerie Léon
Sézanne

This book is by the author of an impressive list of tomes (twenty-three in all) which have dealt largely with a unified theory of disease, and of course a simple system of therapy based on that theory. All disease the theory has it, is based upon a disturbance of the colloids of the body usually in the nature of a flocculation mechanism which in turn is dependent upon humoral instability. The author frankly admits the priority of the ancients in this concept and in his most important chapter (to the reviewer) discusses the various changing views from the times of Hippocrates to the present regarding the importance of the humors in pathological states. He bemoans the fact that the monumental work *Le Nouveau Traité de Médecine* comprising twenty-two volumes and written by fifty-two eminent physicians alludes in no single word or phrase to this important theory.

The second chapter of the volume is devoted to an analysis of the reasons behind the abandonment of "humorism" and the necessity for a quick return because here lies the key to pathologic and therapeutic enigmas. Lumière's theory is based upon the fact that all bodily cells and the circulating fluids are composed of substances present in colloidal states. Life itself according to Lumière is a colloidal set up which, if disturbed results in disease if destroyed in death. Colloidal flocculation results in the sudden entrance into the blood stream of insoluble particles and thus in the symptoms of acute disease. These sudden changes are frequently so slight as to pass unnoticed. Certain

organs however acquire a hypersensitivity to these slight bombardments i.e. in the bronchopulmonary system attacks of asthma may develop. With knowledge of these mechanisms "the mysteries of therapeutics vanish completely."

The process of treating these abnormal humoral states is of the simplest. The author cites the following methods by which the humors may be modified: injections of magnesium hyposulphate, colloid mixtures and hypertonic solutions, hydration and dehydration, hemolysis, hyperthermia, modification of the pH of the blood etc. Magnesium hyposulphate in 10 per cent solution given intravenously is recommended most highly. The book is completed by a series of 26 clinical cases illustrating twenty-six therapeutic triumphs and by these words "Rational and efficacious humoral therapy of the type we have founded inaugurates a new medical epoch." The reviewer sincerely hopes so but is not quite fully convinced.

Blood Groups and Blood Transfusion Alexander S
Wiener 220 pp. Springfield and Baltimore
Charles C Thomas, \$4 00

This book should receive nothing but unequalled approval. It is without doubt the most scholarly and detailed work on the subject of the blood groups in the English language and compares favorably with the German monographs on the subject by Stöffan and Schiff. The book may be read with profit by both the beginner and the student who is well versed in the field since it takes up first principles in great detail and yet delves deeply in the complexities of heredity of the blood groups with the associated subjects of genetics and biometrics. About one-half the book is devoted to individual and species differences in blood groups and much that is new is included particularly in the sections relating to the agglutinogens M and N of Landsteiner and Levine. The latter workers found in addition to the four well-known blood groups that human blood could still further be distinguished by the presence or absence of the new "agglutinogens M and N." Wiener has done a great deal of investigative work on these interesting factors paying particular attention to their medicolegal applications. Whereas when the ordinary blood groups are used the chances of establishing paternity of a child etc. is only about 1 in 6, the addition of test sera containing agglutinogens M and N raises this chance to about 1 in 3. Unfortunately the preparation of types M and N serum and the interpretation of the reactions obtained with unknown samples of blood are both very difficult and to be entrusted only to an undoubted expert in this very narrow field. Wiener has stimulated much interest in the matter and it is probably due at least partly to his work that the New York State Legislature recently passed a law requiring blood grouping tests in all cases of disputed paternity.

The book is exceedingly well printed on good stock

and contains a wealth of references and a good index. There are fifteen pages devoted to the technique of blood transfusion. The writer should be congratulated upon his complete mastery of this rather intricate subject and the book deserves to be made the standard work of reference in the field of blood groups.

Psychology and Health H. Banister. 256 pp. New York. The Macmillan Company. \$2.50.

This is another book by a psychologist on a subject much of which seems to be beyond his ken. Were life and its adjustments all psychology, a psychologist might perhaps adequately handle the topic of psychology and health, but health involves a physical body, subject to traumata, infections, maldevelopments, and malnutrititions, and all the adaptive compromises in physical and mental activities subsequent to the temporary or permanent deletions of function which befall an individual.

The author, watching the gyrations of the tail, forgets too much the dog. He writes well of the inadequacies and fallacies of the theories of Janet, Freud, Jung and Adler. His own theory of sentiment formation is hardly more than a different mode of expressing the thesis that the highest function of the human brain is correlation, which is expressed by an individual in terms of judgment and wisdom.

It is unfortunate that among much that is well said although not new, there appear remarks open to question such as the following: "I do not believe that any breakdown has ever been caused by a study of psychopathology although in certain instances a breakdown may have been precipitated. This I consider a good rather than an evil thing, for the earlier the collapse the greater the chance of permanent recovery." With a greater knowledge of psychiatry it is doubtful if the author would be ignorant of the facts that no mental breakdown is so simple as to be attributable to a single factor and that often the earlier a mental breakdown occurs in life the more difficult is the chance of permanent recovery.

Failure of the Circulation Tinsley R. Harrison. 396 pp. Baltimore. The Williams & Wilkins Company. \$4.50.

Harrison divides failure of the circulation into three types—hypokinetic, hyperkinetic and dyskinetic. The first is more commonly known as shock or collapse, the second as effort syndrome, and the third as organic heart disease leading to congestive failure. He discusses these syndromes in twenty-nine chapters and ends with five chapters describing Mixed Types of Circulatory Failure, Failure of the Coronary Circulation and a Summary.

The book is more a work of reference with a review of literature, and a discussion of physiology than a clinical textbook. It is not a book which would be easy reading for one who was not familiar

with the modern physiology of the circulation. However, this makes it all the more worthy of careful study, for the material in it frequently provides explanations for conditions in circulatory mechanics which physicians find obscure or which they have been content to dismiss without an adequate analysis. One subject which is well covered is the mechanism of congestive failure and a strong case is made for an explanation of it on the basis of "backward failure" as described by James Hope 100 years ago, with increase in venous pressure in either greater or lesser circulation, as opposed to the "forward failure" concept which attributes congestive failure to reduced cardiac output with peripheral anoxemia. Explanations of the genesis of various symptoms and signs such as cardiac hypertrophy and dilatation, dyspnea, Cheyne-Stokes respiration, cardiac asthma, and edema are unusually detailed and the logical presentation of them is very satisfying to one interested in causation. Therapy is less fully considered but the discussion of digitalis is interesting. The author's conclusions that a normal heart rate constitutes tachycardia for the hypertrophied heart, with its difficulty in cellular metabolism of its enlarged fibres, seems well borne out by clinical experience. So too is his decision that "the dilated heart is an inefficient pump for, though it may supply an adequate amount of blood to the tissues, it expends excess energy in order to carry on this work. Heart failure is to be attributed, in the main, to inefficiency rather than to insufficiency of the myocardium."

This book is to be recommended to anyone wishing a summary of the physiology of heart failure in which clinical observations are integrated with an historical survey and experimental data.

Rats, Lice and History Being a study in Biography, which, after twelve preliminary chapters indispensable for the preparation of the Lay Reader, deals with the life history of Typhus Fever. Hans Zinsser. 301 pp. Boston. Little, Brown & Company. \$2.75.

The keynote of this book may be found in the following sentence: "Swords and lances, arrows, machine guns, and even high explosives have had far less power over the fates of the nations than the typhus louse, the plague flea, and the yellow-fever mosquito." The general theme developed by Dr. Zinsser in this most readable account is the rôle that epidemic disease has played in the history of civilization. The earlier chapters cover various of the great epidemics of the past and touch briefly on their effect on contemporary history. On the skeleton of dullest facts he builds, through his literary style, a pleasant flesh which makes an attractive form. Some readers will recognize the first chapter as one that they had already encountered in the pages of the *Atlantic Monthly*, in which Dr. Zinsser pays his respects as an ardent scientist to modern literature.

Clinical and Pathological Application of Spectrum Analysis Walther Gerlach and Werner Gerlach
143 pp London Adam Hilger Limited

This is a very useful short practical manual on the clinical and pathological applications of spectrum analysis. The book is essentially a selection of 'Die Chemische Emissionsspektalanalyse' by Drs Walther and Werner Gerlach translated by Joyce Hilger Twyman and adapted to pathological and forensic problems. Exclusive of the excellent bibliography and index the text comprises about 130 pages devoted mainly to a description of technical procedures. There are included concise discussions of possible variations in technique and of various pitfalls and precautions to be observed.

After describing various light sources and the operation of the optical apparatus the book discusses procedures suitable for taking spectrograms of various types of material. These include the analysis (qualitative and quantitative) of organs, secretions and excretions for the presence of metals and mineral substances. Detailed spectrograms are given for gold, silver, copper, bismuth and lead. The application of the method to specific problems of industrial or forensic importance is interestingly illustrated. Among these are the detection of silicon and aluminium in the lung from pneumoconiosis, the finding of mercury in the urine and the identification of metals in bullet wounds at the site of entrance. There are also useful analysis tables for testing the purity of metals.

The book is tastefully arranged and pleasing in appearance. It should be welcomed especially by workers in toxicology and in the laboratory study of industrial disease. It is particularly valuable to analytical chemists who wish to concentrate upon a highly specialized technique which promises an increasing utility.

What You Should Know about Heart Disease Harold E. B. Pardee Second Edition 127 pp Philadelphia Lea & Febiger \$1.50

This small volume is written for the layman with or without heart disease and is intended to clarify his knowledge of etiology, anatomy, physiology, treatment and prognosis to the end that a better co-operation with the physician may be secured. As is the case with all such books the author has to steer carefully through the sea of controversial matter and in this instance to present what is still unprobed about heart disease only moderately colored with his own point of view. That he is successful in this seems clear and the patient is given enough knowledge and caution to prevent a desire to be his own doctor. In addition to a discussion of causation of heart disease and its manifestations there are chapters on Exercise, Treatment and Climate and Surgical Risks. Some viewpoints do not conform entirely with those of Boston cardiology. Especially notable is the failure to divide the effects of hypertension on the heart from those of coronary arterio-

sclerosis as in the statement that "neither diabetes nor high blood pressure will harm the heart unless the arterial branches supplying blood to the heart muscle are especially affected by arteriosclerosis. Also lead and alcohol are considered as the most important chemical poisons causing arteriosclerosis. Tobacco is thought to be much less harmful."

While the toxic effects from digitals are well described the unpleasant and at times alarming symptoms from nitroglycerine are not mentioned. The importance of contraceptive advice for women with heart disease is not considered and chloroform is advised as an induction anesthetic to precede either in surgical operations.

This is a book to recommend to certain patients who demand more detail about their disease than can sometimes be discussed in the limited time of an office consultation and will be found helpful in the emphasis of important directions in the conduct of their lives.

Diseases of the Mouth and Their Treatment A textbook for practitioners and students of medicine and dentistry Hermann Prinz and Sigmund S. Greenbaum 602 pp Philadelphia Lea & Febiger \$9.00

This volume is presented as a textbook for practitioners and students of medicine and dentistry with an effort made to treat the entire subject matter as a medico-dental problem. This approach makes the book a welcome addition to stomatological literature. The chapters dealing with the oral manifestations of metabolic disturbances of blood dyscrasias of avitaminosis and of the ductless glands of infectious diseases, tropical diseases, animal parasites and skin diseases bring together scattered information on this important but neglected subject and should serve as a convenient and reliable guide for both physician and dentist. These chapters especially will help to clarify some of the many borderline conditions—(The No-Man's Land) which exist between the practice of medicine and dentistry. For this effort alone the book should be highly commended.

The authors have made much freer use of European literature than is common among American writers and this influence is apparent for many dentists of Europe take the full medical training.

This book with its rather different objective should find its way into the libraries of physicians and dentists interested in modern stomatology.

Stammering and Allied Disorders O. S. Bluemel 182 pp New York The Macmillan Company \$2.00

The author believes that "the problem of therapy is simplified if the mechanics of speech are disregarded and if attention is directed to the neurophysiology of speech—one might almost say the biology of speech—in which the production of the

Economic Problems of Medicine A C Christie 242 pp New York The Macmillan Company \$2 00

The author brings together in this book abstracts from the studies of the Committee on the Costs of Medical Care, the report of the Commission on Medical Education, and similar material. His discussion of the data is, on the whole, open minded and judicial although at times he emphasizes certain aspects of specific matters without a similar consideration of opposing points of view. One feels in some places a defensive attitude with reference to the medical profession. He makes a strong plea for greater interest by physicians in preventive measure and indicates quite clearly the advantages of the extension of private practice into this field.

The reviewer is not entirely sympathetic with his attitude with reference to the place of hospitals in medical practice feeling that he is unduly critical of the extension of work by the hospitals in taking care of the sick.

His final chapter which discusses a comprehensive plan for medical care, presents clearly and sympathetically various steps in such changes as would seem to be inevitable.

Particularly to be commended throughout his book is the insistence on the need for coöperation between the medical profession and lay individuals and groups interested in improving the quality of medical care. He rightly emphasizes the need of leadership by the medical profession in developing plans which look toward the extension of the benefits of medical science to all groups in the community and the provision of adequate compensation for those rendering the service.

Diseases of the Rectum and Colon and Their Surgical Treatment J P Lockhart Mummery Second Edition 605 pp Baltimore William Wood & Company \$10 00

The first edition of this work appeared eleven years ago and represented a gathering together and revamping of material included in two previous books by the author one on the rectum and the other on the colon. This present second edition has been largely rewritten and brought quite up to date. The author's long experience as surgeon to St Mark's Hospital for Cancer, Fistula, and Other Diseases of the Rectum, Etc, in London, gives to his opinions the weight of an unusually extensive acquaintance with the diseases of which he writes. St Mark's Hospital is outstanding as an institution where a large amount of proctologic work can be seen in a short period of time.

In reviewing this book, one is impressed with the sound common sense shown in the author's discussion of details in diagnosis and treatment. Although due recognition is given to worthy contributions by other writers, the author does not hesitate to emphasize his own ideas when he thinks they are superior. In connection with rectal bleeding the rôle of an ulcer in a Meckel's diverticulum, as one of the less common causes is emphasized. Numerous

accounts of individual cases of various sorts, many of them unusual and rare, increase the readability of the book. The common and most frequent rectal and anal conditions are systematically covered, each in its own chapter. The ligature operation for hemorrhoids is given preference over other procedures.

The author's operation for correction of complete prolapse of the rectum is given in detail. It is now one of the generally accepted procedures both here and abroad.

In view of the many recent contributions tending to prove almost indisputably that most if not all so called benign or simple strictures of the rectum are due to lymphogranuloma inguinale, it is surprising that no mention of this fact is made in the chapter on "Simple Stricture of the Rectum."

Lockhart Mummery has for some years favored the treatment of cancer of the rectum by simple colostomy, followed by perineal excision of the rectum, except in high tumors. His low mortality of 4 per cent in private cases is a good argument for this procedure and his high five year cure rate is impressive.

This book is complete and well written.

Aids to Surgery Cecil A Joll and Reginald C B Ledlie Sixth Edition 612 pp Baltimore William Wood & Company \$2 75

This very handy pocket edition on surgery is reminiscent of the handbooks on birds and flowers. It is packed full of brief descriptions covering general surgery as well as the specialties, and considers both diagnosis and treatment of the various disease entities. One is truly amazed at what a wealth of accurate information the authors have condensed into 600 pages.

If one has little time for a general review of surgery up-to-date, this volume will give it as briefly as one could ask.

Methods of Treatment Logan Clendening Fifth Edition \$79 pp St Louis The C V Mosby Company \$10 00

According to its preface this book "was planned to furnish an outline of all the methods of treatment in internal medicine." The italics are the reviewer's, because much of the material is presented in the merest outline—and few other methods of treatment than those touched upon can be imagined. In many respects it is up to date—in others it is dogmatically out of date. The illustrations, and much of the text, are primitive for the practicing physician. There are, however, occasional tables and summaries that are entertaining and that under certain circumstances would be very useful. If the reviewer were critically inclined he might prick a hundred holes, but the bottom is so large that still the ship would float. For the medical student it is a comprehensive book for physicians reference it is spread too thin, for the library shelves it is handsome, and we are assured by the publishers, durable, for the reviewer it was well worth the two evenings he spent upon it.

The New England Journal of Medicine

NUMBER 3

The Massachusetts Medical Society

DISLOCATIONS*

BY W. E. GALLIE, M.D.†

Mr President, Ladies and Gentlemen

THE subject of my lecture to night is one which, in an historical sense, is well known to this Society. Many important and original contributions on it have been made by its members. Of these contributors perhaps the most distinguished was Henry Jacob Bigelow who was almost a contemporary of the founder of this Lectureship. His treatise on "The Dislocations of the Hip" is a classic to which the student of surgical pathology still turns when he wishes to acquire basic knowledge of the subject. Perhaps the shade of George Choyne Shattuck, the elder, will pardon the introduction of this subject to-night when he recalls that the study of it brought so much distinction to a surgeon of his own time.

The phase of the subject that has interested me chiefly has been the pathology and treatment of those dislocations that have shown a tendency to recur or to persist in spite of apparently successful reduction. The number of such cases is surprisingly large and is sufficiently impressive to increase greatly one's idea of the importance of dislocation as a cause of permanent disablement.

The dislocation with which all are familiar is the ordinary traumatic dislocation in which the articular surfaces are forcibly separated from one another after the rupture or stretching of the ligaments or tendons which ordinarily hold the bones in apposition. This injury to the ligaments may occur as a transverse tear or as a split between the fibres, or more often as an avulsion of the ligaments from the bones on one or the other side of the joint.

It is not often that one has an opportunity to make a postmortem examination of a dislocation but I have had many opportunities to observe the morbid anatomy at operation and have been struck with the frequency with which dislocations, particularly subcoracoid dislocations of the shoulder, have been accompanied by avulsion of the ligaments from the bone. I

am impressed that in dislocation of the shoulder this avulsion of the capsule from the anterior and lower part of the rim of the glenoid is the chief cause of recurrences. These recurrences are due to the incompleteness with which the avulsed capsule heals down to the bone, either as the result of too early movement of the limb or of failure of the ligaments to return to their normal position. As a result the capsule is much weakened and lengthened so that it no longer is able to prevent forward and downward movement of the head.

The tendency to recurrence of dislocation depends decidedly on the shape of the bones forming the joint. Thus, the hip joint rarely shows a tendency to recurring dislocation because its strength depends on the ball and socket arrangement of the bones and not on the strength of ligaments. In the case of the shoulder the reverse is the case as the shape of the bones is only moderately helpful in preventing dislocation and the strength of ligaments and tendons is very important. In a third type of joint, such as the acromioclavicular and the sternoclavicular, the shape of the bones is of so little importance that the natural tendency of the joint is toward dislocation and this is prevented only by the ligaments. If these are torn or avulsed, the usual result is a permanent dislocation.

The study of a large number of dislocations has impressed on me the importance of congenital abnormalities of the bones and ligaments as a cause of dislocation. I have lately seen three cases of dislocation of the shoulder in which displacement occurred without any trauma whatever. One occurred when the patient made an unusually powerful stroke while swimming; another during an ordinary dive off a six foot dock and the third when reaching suddenly for something above his head. The x-rays showed the glenoid unusually small and the anterior lower lip very low. Examined under anesthesia the head of the humerus could be pushed in and out of the glenoid with a finger tip.

The same observation may be made in regard to recurring dislocation of the patella. In some

*The Shattuck Lecture delivered at the Annual Meeting of the Massachusetts Medical Society, Boston, June 3, 1935.
†Gallie, W. E.,—Professor of Surgery, University of Toronto.
For record and address of author see "This Week's Issue," page 120.

cases, of course, a poorly repaired laceration of the capsule is the sole cause of the bad result but in most of the cases the trouble has no relation to traumatism but is a symmetrical disturbance, occurring in adolescent girls, due to extraordinary laxity of the capsule and absence of a proper outer lip of the patellar groove of the femur. Repetition of the dislocation naturally makes matters worse, but the real cause is the original anatomical abnormality. Even in dislocations in which violent traumatism is the undoubted cause of the first dislocation, there is plenty of evidence that the subsequent tendency to recurrence is often the result of some old anatomical defect such as a low anterior lip on the glenoid.

In an age when operations have become so important in the treatment of fractures it is surprising that they have not become more popular in the treatment of dislocations. The explanation is that the results of conservative treatment are, on the whole, satisfactory. I feel sure, however, that a good many bad results could be prevented if severe ruptures of ligaments were inspected early through an appropriate incision and measures taken to repair the damage accurately. Nobody thinks of leaving a wound of the skin wide open or neglects to bring together the separated fragments of a patella or olecranon, yet how seldom does one hear of a similar operation for the immediate repair of a crucial ligament in the knee or a trapezoid or costoclavicular ligament in the dislocations of the clavicle. Immediate operation has been established as the best treatment for ruptures of the quadriceps and the ligamentum patellae, the ruptures and avulsions of the tendon of the supraspinatus and the capsule of the shoulder, so why not also in those other joint injuries that lead in so many instances to permanent or recurring dislocations?

The time-honoured treatment of dislocations has consisted of the reduction of the displacement and the placing of the limb in such a position that the injured ligament may heal and be restored to normal as quickly as possible. Only those movements are allowed that do not stretch the healing scar. This plan has undoubtedly resulted in satisfactory recovery in the vast majority of these injuries and one must admit at once that the need for any modification of the plan is evident only in the small minority of dislocations that do not respond to the treatment and are left with serious disability. These, unfortunately, are not rare and constitute a considerable problem both in civil and industrial surgery.

A typical example is seen in severe dislocations of the acromioclavicular joint. In the mild injuries the damage to ligaments is limited to the capsule and the amount of displacement is slight, so that, in spite of the fact that the treat-

ment is usually quite futile and the slight amount of displacement almost invariably persists, the function is not disturbed. In the severe dislocations, however, where the coracoclavicular ligaments are ruptured, the clavicle rides up over the acromion and stays there and the result is a deformed and painful and permanently disabled shoulder. It is perfectly simple to reduce the dislocation by manipulation and it may be possible to hold the articular surfaces in fair approximation by apparatus, but the conoid and trapezoid ligaments have been torn across or avulsed and they never repair themselves, so that as soon as the apparatus is removed the displacement recurs.

The obvious remedy for this sort of thing is to perform an operation that will restore the rup-

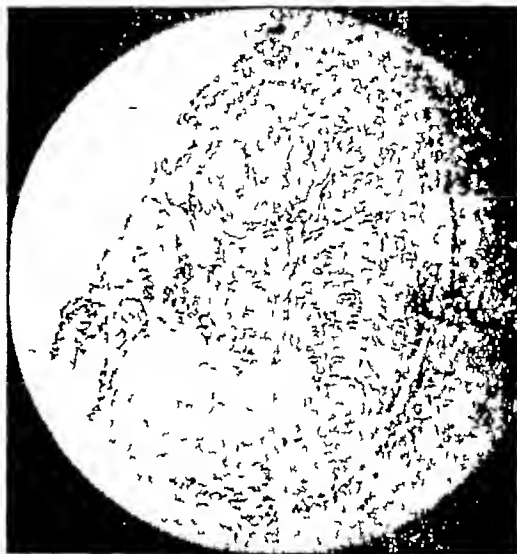

FIG 1. Low power photomicrograph of a cross section of a living suture made from fascia recovered 18 months after implantation.

tured ligaments to something like normal. More or less successful attempts to do this have been made by suturing the torn ligaments with catgut or silk or by tacking down avulsed ligaments with metal tacks. Such operations, however, often prove disappointing because the scar upon which the repair must depend is liable to stretch and so allow the displacement to recur. This has been the common experience in ruptures of the quadriceps and patellar tendons.

The discovery that fascia lata and tendon would continue to live practically unchanged after transplantation from one place to another in the same individual has done much to solve the difficulty. By means of them it is possible either to repair old ligaments or to make new ones and if certain points in technique are observed, to restore joints, even after prolonged disability, to normal.

I have here a few slides which illustrate the well-known viability of transplanted fascia and tendon. The photomicrograph (fig 1) shows a living suture of fascia lata recovered eighteen

months after it was inserted. It demonstrates the way in which a flat strip of fascia will fold up into a cylindrical structure like a tendon and continue to live unchanged, as far as its microscopic appearance is concerned. Figure 2 shows

FIG. 2. High power photomicrograph of living suture from fascia, cut longitudinally recovered 18 months after implantation.

the same strip of fascia cut longitudinally and demonstrates the normal structure of fascia even after eighteen months' transplantation.

If one proposes to repair a rent in a ligament or in a tendon which forms part of the capsule of a joint, no better suture material can be found than living fascia lata. It can be threaded into a needle and moved backwards and forwards like catgut or silk and, if the grip of the ruptured ligament is secure, the repair that will result will be just as strong and permanent as the normal strain requires. Possibly a more perfect living suture can be made from the tendon of the plantaris or the palmaris longus but I have used these only when they have been exposed in the field of the operation.

It is not often, however, that one finds an opportunity to make an immediate attempt to repair a ruptured ligament as it is rare for these patients to come under the care of a surgeon until it is evident that the conservative methods of treatment have failed. By this time the possibility of closing the rent in the ligaments by any type of suturing is gone, owing to the sealing over of the ends of the ligament and their wide separation from one another. Thus in the dislocations of the acromioclavicular joint, there is no chance of repairing the coracoid and trapezoid ligaments even with living sutures. It is in such cases that the making of new ligaments finds a useful place and it is this subject that constitutes the principal part of my lecture.

What I have to recommend has been im-

pressed on me after some satisfactory and many unsatisfactory experiences. The desire to reduce the time of the operation and the risks of infection of the wound have often led to attempts to introduce ligaments where none had existed before and so avoid the more difficult procedure of replacing the injured one. All most invariably these attempts have failed or have been only partially successful and it has been gradually borne in on me that it is usually folly to try to improve on nature. It is now our plan to study the morbid anatomy of the injury as carefully as possible and then, if an operation is decided upon, to try to replace the injured ligament as perfectly as can be done. This, unfortunately, is often difficult and calls for specially designed technique, as in the case of the shoulder and the knee, in order that the ligaments may be properly placed. It is our definite conclusion, however, that the more perfectly the new ligament can be made to resemble the injured one the more perfect will be the final result of the operation.

The technical difficulties of making new ligaments are all associated with attaching the fascia or tendon to the bones and with securing the proper degree of tightness in the new ligament after it has been inserted. Each of these must be discussed in detail.

The fastening of a new ligament to a bone is not so simple as it might seem. Years ago I pointed out that in the operation of "tendon fixation", done for the purpose of converting the tendons of paralyzed muscles into ligaments, it was necessary to bury the scarified tendon in a tunnel in the bone for a distance of an inch or more. Only then would the adhesion of the tendon to the bone be strong enough to prevent it from pulling out. In the case of new ligaments made of fascia, the amount of adhesion is never sufficient to be depended upon and it is always necessary to do something more to make sure that it holds. The most satisfactory plan has been to tie a knot in the end of the fascia which is oversown with fine silk so as to prevent it from untying, and then to draw the new ligament through a tunnel in the bone until the knot lodges against the entrance of it. In this way dependence is placed on the knot instead of on the adhesion of the smooth shiny fascia to the tunnel. (Fig. 3)

Where the new ligament is expected to be subjected to considerable constant or intermittent strain further precautions must be taken in implanting the ligament as strain is very likely to exert destructive pressure on the bone and so allow the new ligament to cut out. I have seen this happen several times after transplantation of the extensor proprius hallucis into the head of the first metatarsal. At first the adhesion of the tendon to the bone was perfectly solid but after a few months the roof of the tunnel in the bone was cut through com-

pletely and the effect of the operation destroyed. To get over this it is a good plan to pass the new ligament through a hole drilled in the bone in the line that the ligament will assume when the operation is completed. By this arrangement the knot is on the opposite side of the bone and cannot possibly cut out (Fig 3)

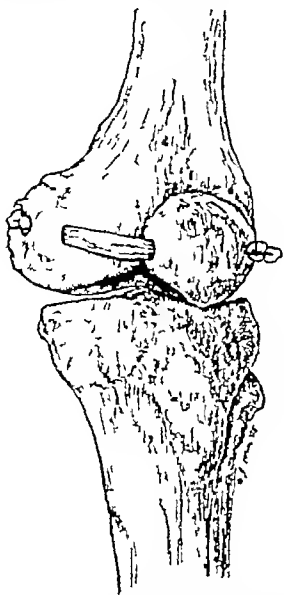

FIG 3 Operation for the prevention of recurring dislocation of the patella. A strip of fascia lata or semitendinosus tendon has been passed through tunnels in the patella and inner condyle of the femur and prevented from slipping by knots tied on the ends of the transplant.

In fastening fascia or tendon to bones by passing them through drill holes, care must be taken that the drill hole is so placed that it does not seriously weaken the bone. These holes never fill up with osseous-tissue and they always weaken the bone at that point so that fracture is liable to occur if the proper force is applied. For this reason it is unwise to bore holes through the clavicle for the insertion of new trapezoid ligaments.

The tightness of the new ligaments after healing is completed and movements are once more allowed is an important factor in the success of the operation. In those cases in which muscles are attached to the ligaments as in the quadriceps, the ligamentum patellae and the supraspinatus, complete success after fascial repair of the ligaments or tendons may be counted on as the muscles take up any slack that may persist. Where no muscles are attached to the ligaments, however, and where tightness is important, as in the internal lateral ligament of the knee the making of new ligaments is apt to come short of perfection. It seems to be impossible either to pull up the new ligament tightly enough or to keep it tight enough afterwards to prevent lateral instability in the joint. The best results may be expected in those joints in which the ligament that has been injured is not under constant tension but is called on to act as a check to too wide a range of movement. Good examples are seen in the operation for recurring dislocations of the patella and of the shoulder.

It is not my intention in this lecture to enter at great length into the anatomical details of the treatment as it is applied to the various joints but simply to pick out here and there examples that will illustrate the principles involved.

Recurring dislocation of the patella is perhaps as simple an example as one can find and it is particularly interesting because the structures involved are so close to the surface. This occurs occasionally as the result of an accident which forces the patella outward and tears the inner portion of the capsule, but it is much more often the result of an anatomical anomaly in which the patellar groove is unusually shallow and the capsule unusually lax. Each time the dislocation occurs the capsule is further stretched and the subsequent synovitis makes matters worse. My first case was that of a soldier who sustained a lateral dislocation of the patella when blown up in a trench. The dislocation was reduced but, owing to the marked knock-knee deformity which was present, the tendency was for the patella to slip off again. He was then operated upon and a plication of the capsule between the patella and the inner condyle of the femur performed. This operation proved futile, as one might expect, and the dislocation recurred within three months. When he came under my care some months later the patella was lying on the lateral aspect of the outer condyle and the man was walking only with the aid of crutches. In the operation which was undertaken the patella and quadriceps tendon and the ligamentum patellae had to be dissected free before the deformity could be reduced and the patella was then tethered to the internal condyle. This was accomplished by means of a strip of the tendo Achillis cut from the same leg and passed through holes in the patella and internal condyle. The result in this case, in spite of a gross knock-knee, has been perfect and now, after the lapse of twenty years, the patella continues to swing normally at the end of its tether and the new ligament can be felt easily stretching from patella to condyle.

Since that first operation we have had many opportunities to test the value of the method but in none has there been a better result. To avoid the risk of seriously weakening the tendo Achillis, however, we have abandoned this source of the new ligament and have used fascia lata or the tendon of the semitendinosus. I think I prefer the latter as it provides a long and very strong tendon, the removal of which seems to cause very little, if any, disability. In several cases in which this tendon was well developed, it was split longitudinally and only half or three-quarters of it removed for the purpose of the transplant. At one end a knot is tied and carefully oversewn with catgut or fine silk. The other end is then drawn through a hole drilled transversely through the patella and

another in the internal condyle of the femur and is finally anchored by tying another knot in it and oversewing with catgut or silk. Thus the new ligament will be fastened to the patella and the femur both by the fibrous adhesion between itself and the tunnels in the bone and by virtue of the knots which cannot pull through the drill holes. It is well to make sure that the new ligament enters the internal condyle at a point which is approximately the centre of the circle through which the patella moves during flexion and extension of the knee, and also that the drill hole in the femur is more or less on the line of a projection of the new ligament so

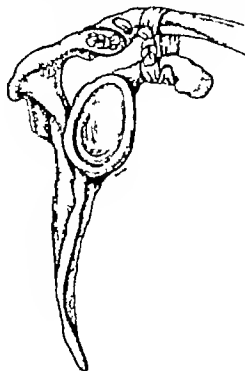

FIG 4 Bunnell's operation for repair of ruptured acromioclavicular ligaments

that the tendency to cut out the cortex of the bone or to wear out the ligament itself at the point at which it enters the bone may be reduced to a minimum (Fig 3) (Gallie and LeMesurier, *Brit J Surg*, 12 289, 1924-25)

Of the persisting or permanent dislocations one of the most interesting is that of the acromioclavicular joint when this is complicated by rupture of the coracoclavicular ligaments. As mentioned above the outer end of the clavicle slips up over the acromion and rests there like a beam on a St Andrew's cross, and no conservative measures will have the slightest effect in bringing about a cure. This is one of the best places in which to apply the principle of replacing the injured ligament by a new one and the technique described by Bunnell is an excellent example of it.

The chief point of the operation is the insertion of a new coracoclavicular ligament to replace the ruptured one. This is done through an incision commencing at the clavicle and extending downward across the tip of the coracoid and along the border of the deltoid (Fig 4). The incision is deepened to expose the clavicle and coracoid thoroughly. A strip of fascia lata $\frac{3}{4}$ " wide and 10' long is then cut from the thigh and passed subperiosteally over

the clavicle and under the coracoid. One of the ends is wrapped once around the coracoid and is finally tied to the other in a triple knot which is carefully oversewn with fine silk to prevent all possibility of loosening. When the knot is being tied the clavicle is pressed down into position and the new ligament is drawn very tight so as to lift the whole scapula up to the clavicle and so make sure of the permanent prevention of redislocation.

Most of the cases that I have seen have come for treatment months after the original injury and by that time the articular cartilage of the acromioclavicular joint had been replaced by fibrous tissue. In these cases the operation just described has been supplemented by the introduction of a new interosseous acromioclavicular ligament. This is inserted in the form of a mattress suture through two drill holes in the end of the clavicle and in the acromion which appear close together in the former acromioclavicular joint. The ends are tied tightly together.

The results of this operation have been excellent. At first we were disappointed because the joint seemed too loose but after we learned

FIG 5 X-ray of knee joint of man operated on by Alwyn Smith of Cardiff in 1915 in which a ruptured anterior cruciate ligament was replaced by the Her-Grove method. The tunnels in the femur and tibia are easily seen. This man has a perfect knee.

the importance of drawing the new trapezoid ligament very tight and lifting the coracoid close up under the clavicle our troubles were over and we have come to expect these patients to return to physical labor after a disability period of three to four months.

This is one of the dislocations which should be treated by immediate operation. There is no chance of a satisfactory healing of the coracoclavicular ligaments, no matter what the treatment, so that one might as well save time by going straight ahead and repairing the damage.

at once. If this is done, the articular surfaces of the joint can be saved and the patient returned to a condition that is practically normal.

I have always thought that one of the most interesting operations performed on joints is that of Hey-Groves in which he introduces new ligaments to replace torn cruciates. The operation for a torn anterior cruciate is the one most often performed as the injury is much more common than in the case of the posterior cruciate. The results are sometimes perfect (Fig 5).

Injury to the posterior cruciate is rare but decidedly disabling. In order to prevent the backward slip of the head of the tibia it is necessary to have a taut posterior cruciate ligament and this means that if a new ligament is to be effective it must be anchored solidly both back and front. To accomplish this the semitendinosus is cut free from its muscle and dissected down to its point of insertion on the antero-internal aspect of the head of the tibia. It is then drawn through a hole drilled through the head of the tibia to appear in the popliteal space just below the attachment of the capsule of the knee to the tibia. In this way it obtains solid anchorage to the tibia. The knee is then opened in front through a split patella incision and the new ligament, threaded into a sharp pointed bodkin, thrust through the posterior capsular ligament and into the synovial tube covering the remains of the old posterior cruciate and then into the joint cavity. The new ligament is then drawn through another drill hole in the inner condyle of the femur which is so placed that it enters the joint at the point of anterior attachment of the cruciate. In this way the tendon of the semitendinosus is made to lie exactly in the position of the old posterior cruciate ligament and when it is drawn taut, to take on perfectly its function. By keeping the bodkin and the tendon buried in the synovial sheath of the old cruciate, one readily makes the new ligament extra-articular, exactly like a true cruciate, so that none, or practically none, of the tendon is exposed in the synovial cavity (Gallie and LeMesurier, *Ann Surg* 85 592 [April] 1927).

The success of these operations on the cruciate ligaments depends on the new ligament maintaining tightness and to make sure of this the greatest care must be taken to keep the tendon drawn taut while it is healing to the tunnels in the bone. I prefer the knot on the end of the tendon as the safest way of preventing the development of slackness. A good many surgeons have been disappointed in the results of these operations for the repair of injuries to the cruciate ligaments, due, practically always, to laxity of the new ligaments. This results from some defect in anchoring the ligament and not from the stretching of it as is so often stated.

But while the dislocations of the patella, clav-

icle and knee provide interesting opportunities for the substitution of new ligaments for old, the really important place for the employment of the principle is in recurring dislocation of the shoulder. This condition is comparatively common and is so disabling that in most instances some form of operative treatment must be tried. Our plan is based on the idea that there is some defect in the capsule in its antero-inferior portion, that is, in the region of the inferior glenohumeral ligament. Usually this defect is at the attachment of the ligament to the glenoid rim and is due to failure of the ligament to heal to the bone. This may result from wide separation of the avulsed ligament from the bone after reduction of the dislocation or from stretching

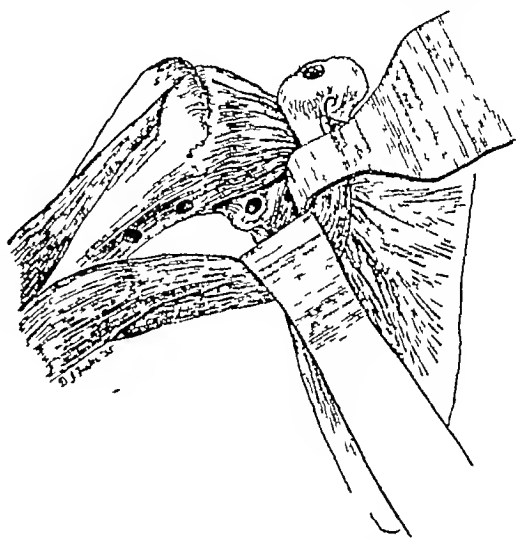

FIG 6 Drawing of dissection by which the antero inferior border of the glenoid is exposed. The combined tendon of the short head of the biceps and the coracobrachialis have been retracted inward and the subscapularis upward so that the capsule of the shoulder joint is exposed and one's finger or an instrument can be placed on the margin of the glenoid.

of the scar before it has become strong. In addition to these recurring dislocations which result from gross damage to the ligaments there are a few which come on without traumatism and are due to congenital laxity of the ligaments. These as well as the traumatic cases call for the introduction of a new inferior glenohumeral ligament which will prevent the head from sliding downward and forward out of the glenoid when the appropriate leverage is applied.

A review of the anatomy of the shoulder joint will show that the anterior lower lip of the glenoid is so remote that in order that a new ligament may be attached to it some new technique must be devised. This has been accomplished by the following steps.

Through an incision along the anterior border of the deltoid from the tip of coracoid to a point opposite the tendon of the pectoralis major, the deltoid is separated from the pectoral till the coracoid and the short head of the biceps and the coracobrachialis are exposed. These are dissected away from the head and neck of the humerus and drawn inward. One then sees

the lower border of the subscapularis as it passes over to its insertion into the lesser tuberosity and by blunt dissection in the areolar tissue below it one is able to get under it and retract it upward and inward. One then sees the capsule of the shoulder as it lies on the prominent lower anterior lip of the glenoid and one can confirm this by pressing the finger against it while the head of the humerus is rotated. This is the spot where the old inferior gleno-humeral ligament is normally attached and it is the spot where the new one must also join the bone (Fig 6). To bring this about a large drill is applied to the anterior lip of the glenoid and is driven backwards, upward and inward through the capsule of the shoulder and the neck of the scapula until it bulges the skin just below the spine of the scapula in the back. The skin over the point of the drill is then incised and the drill, in which an eye has been provided at the tip, comes into view (Fig 7).

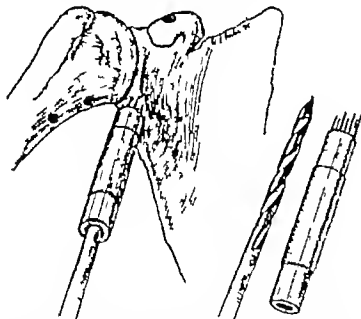

FIG 7. Drawing to illustrate the drilling of the hole through the neck of the scapula. The casing over the drill prevents accidents to the great vessels and nerves.

In the meantime an assistant has cut a strip of fascia lata ten inches long and an inch wide and tied a knot in one end of it and oversewn it with fine silk. The other end of the strip of fascia has been transfixed and ligated with heavy silk which is passed through the eye of the drill. The drill is now withdrawn and with it goes the silk through the hole in the neck of the scapula. In this way the strip of fascia is drawn through the scapula and with a little manipulation the knot on the end of it is pulled through the incision in the skin and finally comes to rest on the posterior surface of the neck of the scapula. Thus the new ligament is solidly anchored to the edge of the glenoid at exactly the right place (Fig 8).

The operation is then completed by drawing the new ligament through holes drilled in the anatomical neck and shaft of the humerus as shown in the diagram (fig 9), and finally through a hole in the tip of the coracoid and anchored there. The new ligament is drawn

sufficiently tight that when healing has occurred the range of motion of the joint, in the direction of abduction and external rotation, will be slightly limited.

This operation has been tested thoroughly on thirty five occasions and has given excellent re-

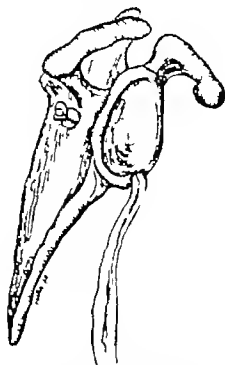

FIG 8. Drawing of scapula to show how the new inferior gleno-humeral ligament is attached to the bone.

sults. One patient was a well known football player and he has played through three seasons since his operation, without mishap. One was a professional lacrosse player and one a champion wrestler. Two were epileptic and in each

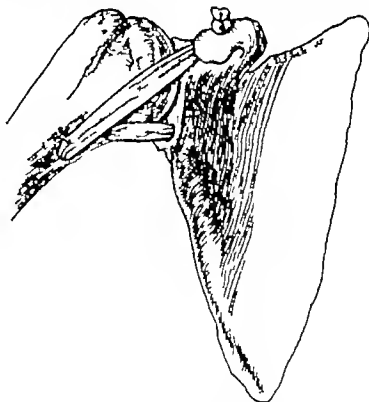

FIG 9. Operation completed with the new inferior gleno-humeral ligament in place and finally attached to the tip of the coracoid process.

of these both shoulders were operated upon. In one of them a recurrence developed six months after the operation and from the story and the subsequent examination I think the new ligament was either broken or torn out of the bone. The same thing happened to one other patient when carrying a heavy pack sack on his shoulder.

ders His arms were stretched up above and behind his head and as the pack toppled backward he tried to hold on to it, with the result that the head of the humerus slipped out All the other thirty-three cases have been cured and are without disability of any kind (Gallie and LeMesurier, Trans Am Surg Assn 45 392, 1927)

One could go on at great length reviewing instances in which ligaments have been repaired or replaced Thus, dislocation of the sternoclavicular joint, if complete, calls for an operation in which a new costoclavicular ligament is introduced Recurring dislocation of the base of the metacarpal bone of the thumb lends itself well to the making of a new capsule Recurring dislocation of the hip can in some instances be cured by plicating the capsule with a living suture of fascia In fact, if one applies the principle of repairing the damage by restoring the injured ligament to as near normal as possible, many causes of permanent disablement will have been removed The most serious difficulty one meets with in these operations is the fastening of the new ligaments to the bone so that when they come into use, they are as tight as their work requires This is particularly so in the case of the internal and external lateral ligaments and the anterior cruciate ligament of the knee In these injuries I have come to think that strips of fascia lata are not so suitable as segments of tendon because it is impossible to make them adhere solidly to holes in the bone Thus in rupture of the external lateral ligament of the knee a thick strip of the tendon of the biceps can be cut free from the muscle, leaving it attached to the fibula, and made to replace the ligament by drawing it through a two inch drill hole in the external condyle If this is drawn tight and anchored with the knee flexed 45° it may be expected to support the joint satisfactorily when healing occurs, for if it was tight in flexion it will certainly be tight when the joint is extended to 180° Similarly in injury to the internal lateral ligament the

tendon of the sartorius or the gracilis can be used to replace the ligament

The chief point of the matter is that, if operative treatment for these injuries has been decided upon, the anatomy of the part must be reviewed carefully and that technique decided upon that will enable the surgeon to restore both the anatomical structure and the function of the injured ligament most perfectly This means that textbook instructions can rarely be followed and that the plan for each operation will have to be decided upon according to the pathological condition found If the few general principles referred to in this lecture are remembered some at least of the pitfalls will be avoided

The preparation of the material for my lecture tonight has led me into several paths of reading that have given me the greatest pleasure One was the very interesting history of the Massachusetts Medical Society written by Dr Walter L Burrage In this I found that in his will, George Cheyne Shattuck left a sum of money which was to provide for the collection and publication of historical or other essays on the climate or the diseases of Massachusetts I knew nothing of the climate of Massachusetts except that when I am here the sun always shines, but I did remember that many distinguished members of this society had studied dislocations, so I concluded that this condition must be particularly prevalent in Massachusetts and could therefore be considered a suitable subject for this Lecture Another revelation to me, derived from Dr Burrage's book, was the astounding way in which the distinguished names of a hundred years and more ago, still appear and with equal distinction as the members of this society today Coming from a new country, as I do, I envy you in the tradition you have built about our profession For this and many other reasons I regard as the highest honor the invitation you have given me to deliver the Shattuck Lecture and to add my name to the list of distinguished men who have already addressed you

THE RETICULOCYTE RESPONSE IN GUINEA PIGS
FOLLOWING THE ORAL ADMINISTRATION OF
CERTAIN ANTI ANEMIC SUBSTANCES*

BY D K MILLER, M.D.,† AND C P RHOADS, M.D.‡

AMONG the different methods which have been suggested for testing the potency of the purified fractions of liver which are used in the treatment of pernicious anemia the procedure of Jacobson¹ has received particular attention. This procedure depends upon the fact that a certain number of normal guinea pigs react to the injection of particular anti anemic substances by a rise in the percentage and absolute number of reticulocytes in the peripheral circulation. Experiments which are based upon this observation and which are concerned with the relationship of certain dietary substances to hematopoiesis have been made in this laboratory. The substances which were tested were fed rather than injected parenterally. The results are of interest for two reasons. First, they confirm the experiments of Jacobson which indicate that the mechanism described by Castle² for pernicious anemia is also operative in the causation of reticulocyte rises in the guinea pig. Secondly, they show that increases in the number of circulating reticulocytes which are similar in degree, duration and time of occurrence to those obtained by Jacobson¹ may be induced by potent, anti anemic substances which are orally as well as parenterally administered.

METHODS

Adult male guinea pigs weighing from 500 to 600 grams were employed. They were kept in groups of four in metal cages with shavings as bedding. A standard diet of oats, hay, and cabbage was employed. All of the substances tested were fed daily from graduated pipettes to make certain that the desired amounts were taken. Reticulocyte counts were made daily. Blood obtained by pricking an ear vein was smeared on cover slips upon which a film of brilliant cresyl blue had been dried previously. The preparations were then stained by Wright's method. Five hundred cells were counted. An increase in the average number of reticulocytes to a value of over 2 per cent was considered to be a positive response.

The rice polishings concentrate used was prepared by the Burroughs-Wellcome laboratory. It is known to contain 33 rat-growth units of vitamin B₁ and 0.5 rat growth units of vitamin

B₁₂ (G) per gram. This material has been tested on human beings with pernicious anemia and has proved to be a source of dietary anti anemic factor. Miller and Rhoads⁴ The autolyzed yeast concentrate (Vegex) has been reported by Strauss and Castle⁵ to be a source of dietary anti anemic factor. The alcoholic extracts of vegex were prepared by bringing a 50 per cent water solution of vegex to the desired concentration of alcohol, stirring thoroughly, filtering through paper, and evaporating the filtrate in vacuo to a volume which was equal to the volume of Vegex originally extracted.

Certain of the substances tested were administered after incubation with normal human gastric juice according to the technique of Strauss and Castle⁵. The gastric juice was obtained after the intramuscular injection of 0.5 cc. of a 1:1000 solution of histamine hydrochloride. Twelve grams of the substance to be tested were mixed with 160 cc. of gastric juice and incubated for one hour at 37°C. The pH was adjusted before using to 5.5 with concentrated NaOH.

THE SELECTION OF ANIMALS

As shown in table 1 eighty five guinea pigs were tested for rises in reticulocyte percentages.

TABLE 1

TESTS OF THE EFFECT ON THE RETICULOCYTES OF NORMAL GUINEA PIGS OF FEEDING 0.6 GM LIVER EXTRACT No. 343 DAILY

Diet Supplement	No of Anti-mals	No of Animals Reacting with a Rise of Reticulocytes	Level of Response	Day of Response

‡The term vitamin B₁₂(O) is used in this publication to refer only to the thermostable vitamin which is required by rats for growth. It has no reference to the heat labile fraction of the water soluble vitamin B₁₂ complex known as factor PP which is preventative and curative of canine black tongue and of human pellagra.

greater than 18 One positive test was considered sufficient to warrant classifying the animal as one which was capable of giving a reticulocyte response Such animals were segregated and after a suitable interval were employed to test substances of unknown potency

TESTS OF RICE POLISHINGS CONCENTRATE AND OF GASTRIC JUICE

The results of four tests of these substances are presented in table 2 In the first the effect

TABLE 2
TESTS OF THE EFFECT ON THE RETICULOCTES OF REACTIVE GUINEA PIGS OF FEEDING RICE POLISHINGS CONCENTRATE AND GASTRIC JUICE

Diet Supplement	No of An- imals Tested	No of An- imals Giv- ing Re- sponse	Level of Response	Day of Response
Rice polishings concentrate 1 Gm q d	7	0	—	—
Rice polishings concentrate—gastric juice incubate 4 cc q d	3	3	55 8%	11th 13th
Autoclaved rice polishings concentrate—gastric juice incubate 4 cc q d	4	3	23 6%	8th 9th
Gastric juice alone 2 cc q d	3	—	—	—

of feeding one gram daily of rice polishings concentrate to seven reactive guinea pigs was investigated No reticulocyte rise occurred in any animal This fact is considered to be evidence that the substance is without antianemic potency if it is administered alone In a second test an incubated mixture of the rice polishings concentrate with normal gastric juice was fed to three guinea pigs which had been shown to be capable of responding to the administration of potent material A reticulocyte rise to between 5 and 58 per cent was effective in all three animals between the eleventh and thirteenth days This result is evidence that some constituent of the rice polishings concentrate was so altered by incubation with normal gastric juice that it gained an hematopoietic potency which had been lacking previously The third test is similar to the second except that the rice

polishings concentrate was autoclaved for four hours at neutrality before using in order to eliminate any effect which might be due to its high content of vitamin B₁ Three of the four reactive animals tested responded with a rise in reticulocytes to between 2 and 36 per cent on the eighth and ninth days after the treatment was begun Gastric juice alone was fed in a fourth test and no response was effected

TESTS OF AUTOLYZED YEAST (VEGEX) AND VEGEX EXTRACTS

Untreated vegex was tested by feeding one gram daily to each of five guinea pigs which had been proved to be capable of responding by a reticulocyte rise to the administration of liver extract No effect was obtained, as would be expected from the report of Strauss and Castle⁵ After the vegex had been treated by incubation with normal gastric juice, however, the feeding of one gram daily resulted in a positive response in three out of five instances Reticulocyte rises to from 22 to 34 per cent occurred on the ninth to the eleventh days after treatment was begun

Vegex gastric juice incubate 4 cc q d	5	3	22 3 4%	9th 11th
95% alcoholic extract vegex	4	0	—	—
90% alcoholic extract vegex—gastric juice incubate 4 cc q d	2	2	32 5 4%	12th

In a third test four known reactive animals were fed a 95 per cent alcoholic extract of vegex without effecting any change in the reticulocyte levels When a similar extract was fed after incubation with gastric juice both of the two test animals gave positive responses The reticulocytes rose to between 32 and 54 per cent between the tenth and twelfth days

This result is in keeping with the report of Strauss and Castle⁶ concerning the hematopoietic potency of alcoholic extracts of vegex after incubation with gastric juice

DISCUSSION

The usefulness of the reticulocyte rise in reactive guinea pigs as a test for potent anti anemic substances can be established in only one way. It must be shown clearly that the induction of the reticulocyte rise depends upon the same pathological mechanism as that which obtains in the human being with pernicious anemia. That mechanism is not wholly clear but one finding is encountered with great constancy. The gastric juice of the patient with pernicious anemia is incapable of converting certain dietary constituents into a factor which is required for normal blood formation. Such a conversion can be effected by normal gastric juice. From these two facts certain conclusions as to the etiology of pernicious anemia have been drawn. The experiments reported indicate that the factors inducing the reticulocyte rise in the guinea pig

are similar to those causing hematopoiesis in human beings with pernicious anemia. In the absence of a crystalline substance, however, it cannot be said with absolute certainty that the substance inducing the reticulocyte production is the same in the guinea pig as in the patient with pernicious anemia.

CONCLUSION

The reticulocyte response in suitable reactive guinea pigs presents certain similarities in its causative mechanism to that obtaining in human beings with pernicious anemia.

THE EARLY CLASSIFICATION AND EARLY DIAGNOSIS OF CANCER OF THE BRONCHUS*

With An Analysis of Thirty One Case Reports, Including Three Pathological Diagnostic Errors

BY MILTON S. LLOYD, M.D.†

AS our knowledge of carcinoma of the bronchus increases, our opinions must be revised. A study of the literature on the subject both here and abroad leads only to confusion in diagnosis and hopelessness in prognosis. The author is of the opinion, however, that, with a well-ordered knowledge of the clinical syndromes of the disease and the proper application of our present technical methods the diagnosis can always be made early. Rapid strides are at present being made in the field of thoracic surgery and the anatomical structure of the lung offers some advantages for the total extirpation of malignant tumors. The author believes therefore that a number of these growths if found early and favorably situated, should be placed together with carcinoma of the larynx, among the malignancies with a definitely hopeful prognosis.

To draw these conclusions from a series of cases, few of whom were diagnosed early and practically all of whom are dead, would seem, at first sight, to be unjustifiable. But an analysis of the data here presented and a study of many other case reports, both published and

unpublished, show that symptoms definitely indicative of carcinoma of the bronchus, existed and persisted, frequently for months and some times for years before even an x ray of the chest was taken. B. M. Fried¹ in one of the best treatments of the subject, yet to appear in print, states reassuringly, "The frequency of metastases in bronchiogenic cancer in man diminishes with the distance from the central axis of the body." At the same time from the admittedly late cases now being seen, records of successful surgical removals are appearing in the literature with increasing frequency.

Two important conclusions therefore appear. The first is that the early diagnosis of cancer of the bronchus is an urgent necessity. The second is that the clinical apprehension of the disease lags unjustifiably, in view of the mass of information extant upon the subject. The reason for this retardation undoubtedly arises from the fact that little has been done to lead the clinician through the multiplicity of confusing details which may beset the early diagnosis. A departure from the usual methods of treatment would appear to be indicated. To say the least the subject needs further study and clarification.

If in the following lines, the author presumes to take issue with many of the well known au

thorities, it is not because he wishes in any way to deprecate their efforts. On the contrary he is willing to acknowledge them as the source, either directly or indirectly, of most of the information and all the inspiration of which he is possessed.

CLASSIFICATION

A clinical classification which serves no purpose for diagnosis, prognosis or treatment is useless. Miller and Jones² in their study of thirty-two cases, laid down a classification of ten types. There is little however in their grouping to assist in rounding out clinical syndromes. Fried¹ concludes "From the material studied it is apparent that a reasonable classification of bronchiogenic cancer based on clinical features is as superfluous at the present time as that based upon their gross anatomy." The present author does not feel that this statement applies to-day. It must be realized that any attempt to study the early clinical manifestation of carcinoma of the bronchus from the end picture seen upon the autopsy table, cannot be more productive of results than an attempt to learn the causes of the World War by visiting the battle fields of France. The only way to master the clinical course of cancer of the bronchus is to study it clinically.

Fortunately the anatomy of the chest and the mechanics of respiration are such, that a simple and sane subdivision of these tumors, covering their common and important symptoms, can be easily made. If the thoracic cavity is examined dimensionally, it will be found that the bifurcation of the trachea is situated almost exactly at the geometric centre of the air bearing tissue of the lungs. As Nelson³ states, "This can be expressed diagrammatically, by imagining the chest to be a sphere, the centre of which is the bifurcation of the trachea." Departing from this point the cavity may be divided into three zones, viz, a central or hilar zone, a middle or bronchial zone and a peripheral or parenchymal zone. The clinical phenomena will depend in large part upon the zone in which the new growth primarily takes origin. The cause of symptoms in the three groups may be assigned as follows—

Central Zone.....Hilus Infiltration
Middle Zone.....Bronchial Obstruction
Peripheral Zone.....Centrifugal Expansion

To these must be added the rarer types of "Miliary Carcinosis," which are principally of anatomicopathological interest and the type of carcinoma which is "bronchiectatic" or according to Letulle "cavitaire d'emblée" and which should be in the early stages diagnosed by an accidental bronchoscopic finding.

Tumors of this group, fortunately the least common, spring from the lower part of the trachea and from the stem bronchi. Due to the solid structure of the air passages in this

region dissemination of malignant cells is in part controlled. Infiltration takes place by extension along the bronchial walls or the vascular structures, into the lung and the hilar glands or by direct invasion of the surrounding tissues. Their anatomical location and their proximity to important structures, may bring dysfunction of other organs or remote symptoms into the picture. On the other hand obstruction, due to the ample size of the airways, occurs late.

Bronchial Obstructive Group

These growths arise in the second division or smaller bronchi. From the periphery of the lung up to this point, drainage is effected, principally by bronchial and ciliary movements.

HILUS INFILTRATING GROUP

FIG 1 Case 1. Carcinoma arising in the lower end of the trachea and involving the esophagus by direct extension. Principal symptoms: substernal pain four months; dysphagia two weeks.

There ensues the usual train of the clinical manifestations of impaired drainage up to complete obstruction with atelectasis or pneumonia. The paths of infiltration are similar to those in the central zone group, but their distance from the mediastinal structures delays the direct involvement of other organs.

It seems unnecessary under this heading, to introduce, as has been done by some authors, special subdivisions, depending upon the presence or absence of cavity or the varying degree of patency of the bronchus.

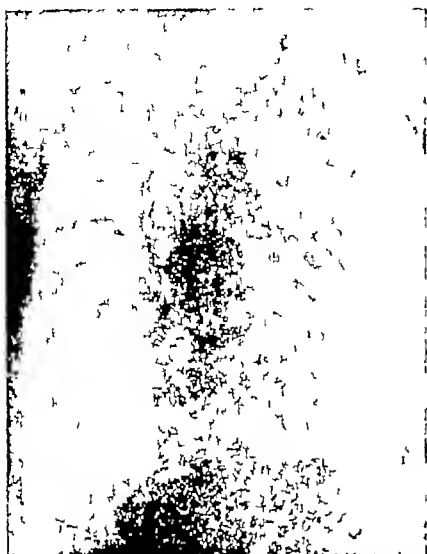

FIG 2 Case 1. X-ray photograph of the barium swallow. The pipe stem character of the middle of the tube is notable. A slight filling defect at the level of the left posterior intercostal space corresponded with the site of the lesion.

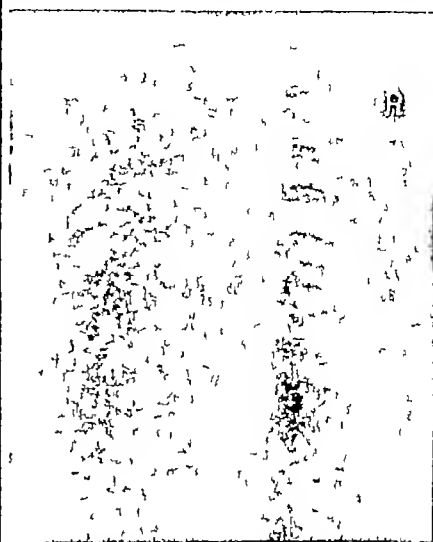

FIG 4 Case 3. Carcinoma arising in the left stem bronchus. Principal symptoms were pain left upper chest and neck four months, cough and dyspnea two months, hemoptysis two weeks. Almost complete absence of air from the left lung. Striations may be seen in the right lung similar to those on the left side in Fig 2. An exploratory thoracotomy showed massive involvement of the mediastinum.

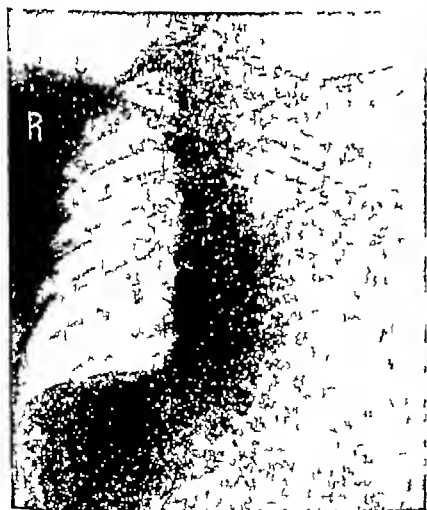

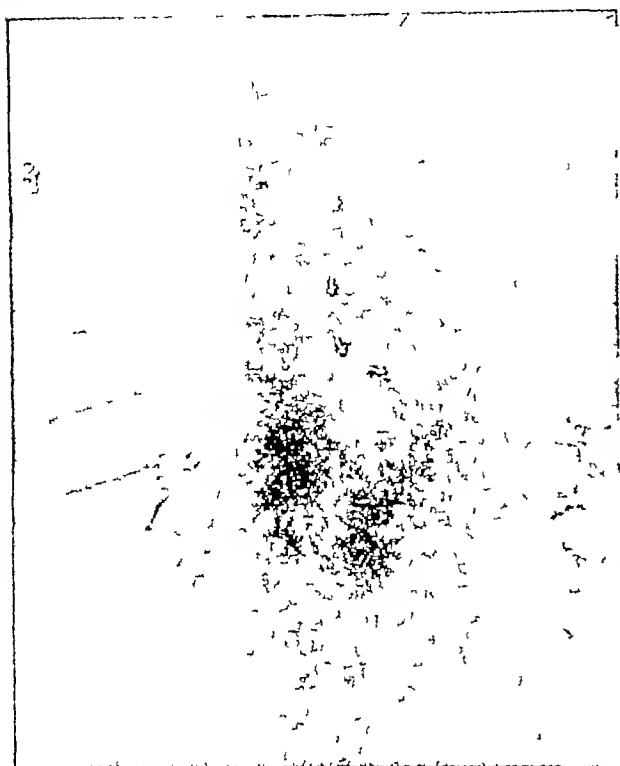

FIG 3 Case 2. Carcinoma arising in the left stem bronchus. Principal symptoms: cough, dyspnea, substernal pain seen in months, very severe pain left side of neck and left arm, three months. Marked loss of volume of the left lung is visible, together with radiating striations representing lymphatic extension into the pulmonary field. Such films are frequently interpreted as "interlobar plastic pleurisy." Bronchoscopy fourteen weeks prior to this x-ray showed the secondary characteristics of infiltrating new growth. Biopsy however was reported "fibrotic nodules."

FIG 5 Case 4. Carcinoma arising in the right stem bronchus, level of the middle lobe bronchus. Principal symptoms: cough five months, pain three months, hemoptysis on week. Most important physical sign: a thymoid wheeze. X-ray shows shifting of the mediastinum downward, rotation of the left rib cage (retroached) and early lymphatic nodules and vascular infiltration.

BRONCHIAL OBSTRUCTIVE GROUP

FIG 6 Case 5 Carcinoma arising in the left upper lobe bronchus. Principal symptoms: bronchitis, pain, dyspnea, cough and hemoptysis six months. Lipiodol injection reveals marked retraction of the trachea. The upper lobe is completely atelectatic and a cavity with fluid level is present in the apex. This patient lived for two years after this picture was taken without treatment.

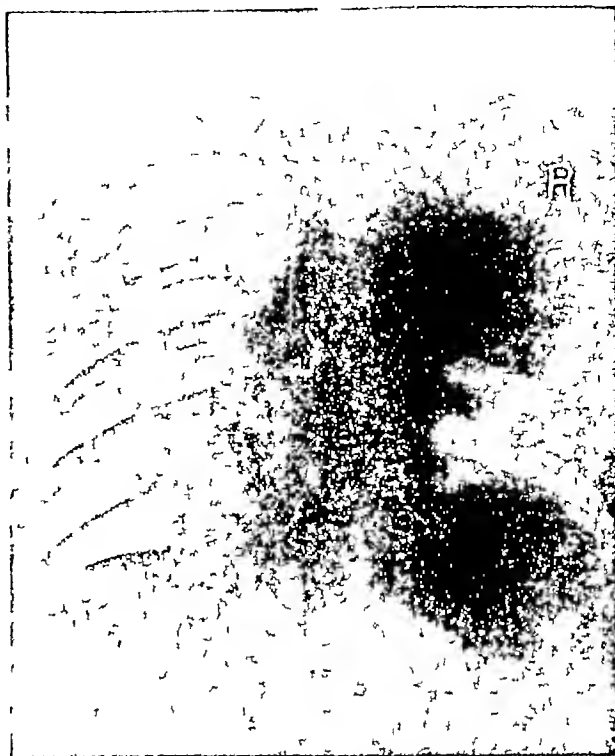

FIG 8 Case 7 Advanced carcinoma involving the right upper and middle lobe bronchi. In this instance the phrenic nerve is also involved.

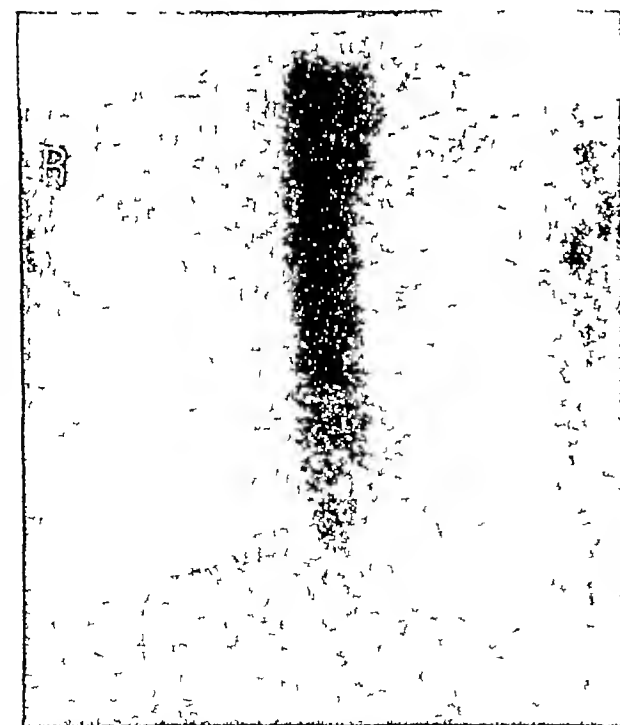

FIG 7 Case 6 Carcinoma arising in the right upper lobe bronchus. Principal symptoms: cough, hemoptysis one year, dyspnea two weeks. Most important physical signs: asthmatic wheeze and after breathing. Complete atelectasis of the right upper lobe with typical rotation of the interlobar fissure.

FIG 9 Case 8 Early carcinoma arising in a second division branch of the right lower lobe bronchus (fourth division from trachea). Although this growth was no larger than the head of a match, impaired drainage with early atelectasis is already present. The interlobar fissure has rotated downward one interspace. (Interlobar fissure retouched.)

FIG 10. Case 9. Carcinoma involving the right lower and middle lobe bronchi. This patient had a metastatic growth in the brain. (Interlobar fissure retouched.)

FIG 11. Case 10. Lipiodol injection in a case of carcinoma of the right lower lobe. The patient had just recovered from "pneumonia." This examination demonstrated the necessity for bronchoscopy and forestalled the proposed cure of a winter in Florida.

FIG 12. Case 9. Repeat x ray following the spontaneous evacuation of the bronchus of a plug of tissue and mucus. The fallacy of introducing a separate classification to cover this eventuality is obvious. In spite of restored patency of the bronchial lumen, the lower lobe has suffered a loss of volume as compared with fig 10 taken five days previously. (Interlobar fissure retouched.)

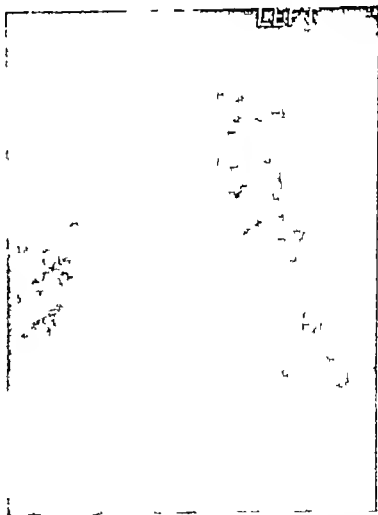

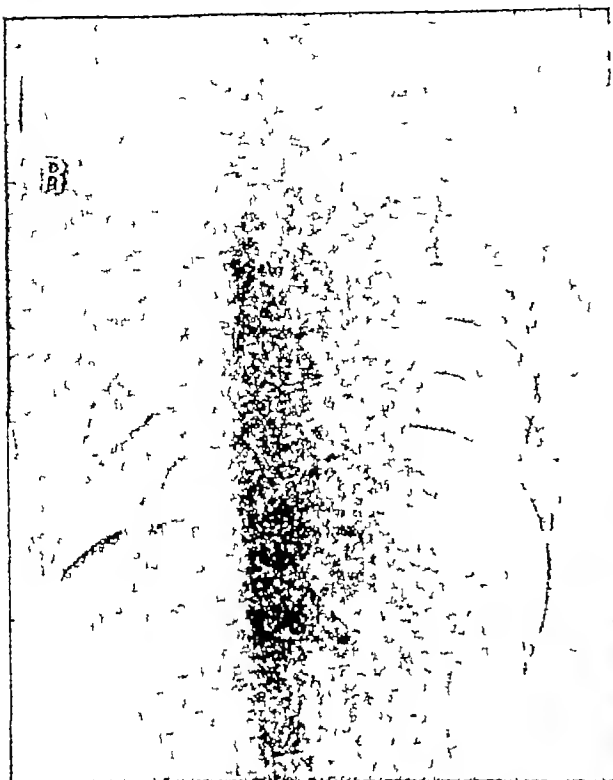

FIG 13. Case 11. Carcinoma of the right upper lobe bronchus simulating lung abscess. Principal symptoms eight ounces daily foul expectoration, bubbling of the fingers. A cavity with fluid level is visible. Bronchoscopy negative for new growth. Diagnosis made by biopsy at second stage thoracotomy for drainage of abscess.

CENTRIFUGAL EXPANSIVE GROUP

FIG 14 Case 12 Carcinoma arising in the parenchyma of the left upper lobe and contacting the chest wall below the scapula. Localization was made by x-ray and thoracoscopy and diagnosis by punch biopsy. In this case limited movement on the left side was the indication for x-ray of the chest.

FIG 16 Case 14 Carcinoma arising in the parenchyma of the left upper lobe. The shadow of the tumor is obscured by the presence of an effusion. Principal symptom very severe pain of the intercostal neuralgia type. Diagnosis made by biopsy of a left axillary gland.

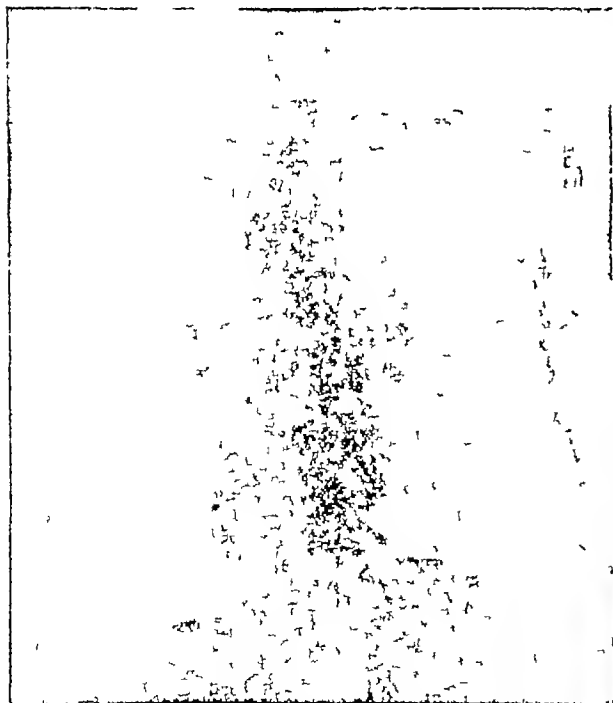

FIG 15 Case 13 Carcinoma arising in the parenchyma of the left upper lobe. Principal symptom severe pain left shoulder. The remaining features of the syndrome of superior pulmonary sulcus tumor were absent. Marked pressure distortion and destruction of bone can be seen. With the exception of evidence of external pressure on the tracheal wall bronchoscopy was negative. Diagnosis made at operation.

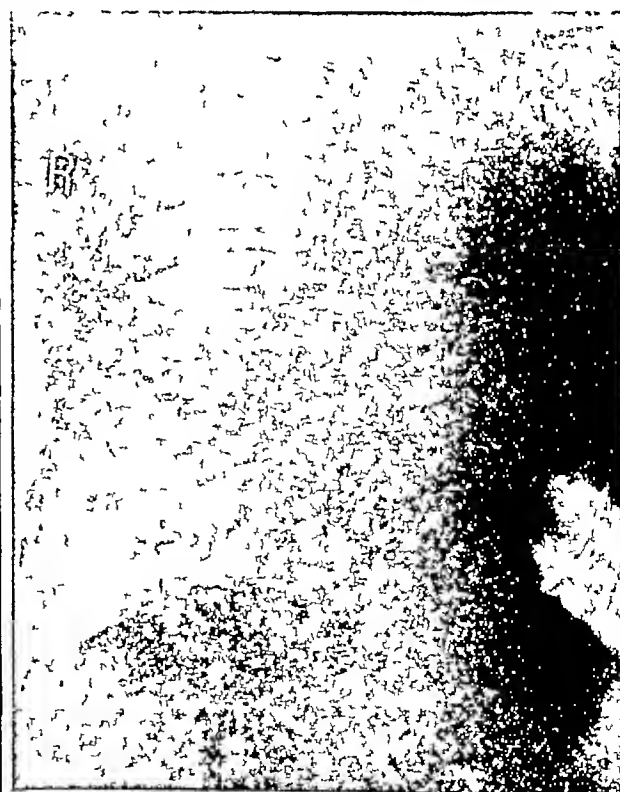

FIG 17 Case 14 Repeat x-ray two months later. The gradual involvement of an entire hemi-thorax obliterates the group characteristics and makes classification from the end picture almost a clinical impossibility.

FIG. 18. Case 18. Complete atelectasis of the left lower lung. Symptoms entirely gastric. Biopsy at this time reported "carcinoma" later changed to "adenoma." Note elevation of the diaphragm and shadow at the first interspace simulating cavity with fluid level.

FIG. 19. Case 18. X-ray taken ten months later. Condition has remained the same with no evidence of recurrence for three and one-half years. The diaphragm remains elevated, probably due to adhesions. The patient had been operated on twice for gastric ulcer and once for adhesions and ventral hernia.

Centrifugal Expansive Group

A cancer arising in the air bearing tissue of the lung (terminal bronchiole or alveolus) is surrounded by a soft spongy medium offering reduced mechanical resistance to its expansion and that resistance approaches equality on all sides. The resultant tumor is round and frequently sharply defined and continues to grow centrifugally, until some structure is reached, which alters the destiny of its shape or course. The most frequently involved structures are the pleura and the chest wall. Without involvement of the chest wall these tumors are the most likely to be overlooked clinically in the early stages and are the most difficult in which to obtain early pathological and diagnostic confirmation. With involvement of the chest wall, the diagnosis is simplified but the prognosis is impaired.

EARLY DIAGNOSIS

Like any other disease cancer of the bronchus cannot be diagnosed in its early stages by any single sign, single instrument or single procedure. The clinician must be alert to its possible existence in every syndrome, however trivial, involving the health of the lungs and the specialist must often be prepared to exhaust every means at his disposal, before a final diagnosis is established.

Symptomatology

The complaints presented by the patient, in order of frequency, follow the percentages given refer to the particular series of cases reported herewith, the less common symptoms being placed under their separate groups.

a Cough	_____	Early 90%	late 10%
b Pain	_____	Early 70%	late 20%
c Dyspnea	_____	Early 40%	late 30%
d Pneumonitis (bronchitis colds grippe influenza, pneumonia)	_____	Early 40%	late 30%
e Hemoptysis	_____	Early 30%	late 20%
f Loss of weight	_____	Early 30%	late 65%
g Asthma	_____	Early 5%	late 15%

It must be noted that the early symptoms of cancer of the bronchus are, as a rule, suggestive of some much less important disturbance. Their true significance, however, soon reveals itself in the "atypical" onset or course, which will, subsequently, be examined in greater detail.

Hilus Infiltrating Group

Symptoms may be local or remote, depending upon the structures involved. Substernal pain and discomfort and pain in the shoulder radiating up the neck or down the arm via the phrenic nerve and the cervical or brachial plexus, are the outstanding complaints. The pain varies from a sense of discomfiting tightness under the sternum to a constant, unbearable, shoulder ache from which the patient desperately seeks relief.

It is not, however, of the localized burning character, below the sternum, associated with acute bronchitis

There may be difficulty in swallowing, gastric dysfunction, hoarseness or cardiac disturbance, due to direct extension of the growth, or involvement of the nerve leading to the organ concerned

Cough, in the opinion of the writer, is generally present much earlier than admitted by the patient in the usual history, due to the association of tuberculosis with chronic cough and the racial abhorrence and apprehension of that disease, and hemoptysis and dyspnea are important, if not always early complaints

Bronchial Obstructive Group

With this group, cough is the chief complaint. Due to the impairment of drainage, there is retention of secretions and a localized bronchitis. The patients find difficulty in "clearing the lungs" and the cough takes on the character of a paroxysm, in many cases, in their effort to obtain relief. The amount of sputum is increased in nearly all cases, and it frequently contains blood. Frank hemoptysis may appear early and then disappear without recurrence for an interval of weeks or months.

In this group, is also heard, particularly the story of repeated "colds" with chills and fever, from which the patient may have been confined to bed on more than one occasion, with recovery "almost but not quite complete." At the same time there is a gradually increasing difficulty in obtaining sufficient air, which finally amounts to a shortness of breath. There is generally some degree of pain which may best be described as a pulmonary distress, or it may accompany the episodes of fever in the nature of a pleurisy, lasting or evanescent.

Remote symptoms are relatively few, except when a rapidly developing atelectasis on the left side causes gastric disturbance by elevation of the diaphragm.

Centrifugal Expansive Group

The peripheral zone group probably have a "silent period", during the earliest stages, when the patient may realize that something is amiss, inside the chest cavity, but can scarcely describe his sensations. The earliest case seen by the author in this group, described his feeling as a "sense of oppression" and a "weakness in the lung." Later, however, when the pleura is involved, pain may be stabbing and severe. If the intercostal nerves are directly affected there may be a neuralgia of such severity as to require blocking of the trunks at the vertebrae, and when the growths are apically placed, pain in the shoulder closely simulates that experienced with the central zone group. (The relation of the so-called Superior Sulcus

Tumor⁵ to these intrapulmonary apical growths, has not, at this writing, been definitely determined.)

Cough, while generally present at an early date, is not distressing and hemoptysis, in this series, did not occur.

Physical Examination

The most constant and most important physical sign is a limitation of movement on the side of the affected hemithorax. Laennec's contraction, with drooping of the shoulder and "winging" of the scapula may be marked. The trachea is frequently shifted to the affected side. Neumann⁶, speaking in reference to cancer of the upper lobe, states, "The most valuable diagnostic sign of these cases is a solid (starre) dullness in the medial portion of the infraclavicular fossa, which encroaches upon the manubrium, even reaching its opposite border, but which does not fuse with the cardiac dullness." While this may be true of the far-advanced cases, it cannot be said to apply to the early, or even the moderately advanced cases, regardless of their site of origin. On the contrary, shifting of the mediastinum more frequently carries the hyperresonant note of the emphysematous contralateral lung, toward the affected side.

Hilus Infiltrating Group

The central zone tumors present the greatest diversity of signs. Horner's syndrome⁷, inequality of the pupils, paralysis of the vocal cords, slowing or irregularity of the heart beat, diminished respiratory excursion (sympathetic, phrenic or vagus nerve involvement), stasis in the jugular and mammary veins or edema of the arm. The percussion note is not altered early in these cases, except for a widening of the mediastinal dullness, which is difficult to demonstrate dependably. The diagnosis should be made by other methods before the later physical signs appear.

Bronchial Obstructive Group

Growths in the middle zone are nearly always accompanied by some degree of atelectasis and consolidation or effusion, with an associated decrease in resonance and fremitus. Signs heard through the stethoscope vary from day to day, even from hour to hour, depending on the patency of the bronchus. They are constant, however, in the broader sense, that they always indicate a unilateral bronchitis or asthma, a localized atelectasis or effusion or one of their combinations. Even when these patients are suffering from "pneumonia" with high fever and prostration, the bronchophony is subdued and mixed with a variety of rhonchi and never corresponds in intensity with the degree of dullness obtained upon percussion, but is roughly parallel with that normally heard in the interscapular area. The partially atelectatic, par-

tially consolidated lobe serves as a filter, suppressing the finer, but allowing the louder sounds to come through. If the patient is asked to take a few deep breaths, pronouncing the word "nine" with each expiration, the differentiation of the consolidation of cancer and that of true pneumonia may be dramatized. An alternation of bronchophony during expiration and silence during inspiration will replace the usual accentuation of both phases, found in true pneumonia.

These episodes terminate in "unresolved pneumonia", a term which has entirely lost its meaning and has no place in the medical vocabulary of to-day.

Among the most positive signs, must be mentioned the asthmatic wheeze and after breathing. These may be only rarely present in the early cases, but when recognized, are pathognomonic of obstruction to the lumen of a bronchus. The asthmatic wheeze must not be confused with the laryngeal wheeze sometimes produced by a nervous patient, when respiration is under conscious control. The best way to familiarize oneself with this sound is to spend a few sessions in a bronchoscopic clinic where it can frequently be heard through the bronchoscope with unmistakable clearness and intensity.

Centrifugal Expansive Group

It is possible for tumors in the peripheral zone to attain considerable proportions without revealing any other clue to their presence than diminished respiratory movement. Rounded tumors may also be tangential with the chest wall below the scapula and so escape detection in the early stages.

On the other hand early invasion of the pleura produces local signs which simulate, or represent when present, a circumscribed effusion while apical infiltrations require as far as physical signs are concerned, careful differentiation from the fibrotic type of tuberculosis. Enlargements of the regional lymph nodes axillary or cervical are not uncommonly, an early finding.

X Ray Signs

In the general run of cases the x ray may be depended upon to reveal more information than any other method of examination. The findings are characteristic for each of the three groups.

Hilus Infiltrating Group

Due to the absence of air as a contrast medium the presence of these tumors in the early stages is most easily overlooked. Widening of the mediastinal shadow or bulging of the tumor mass into the airways or the lung field and fixity, rigidity or deformity of the esophageal lumen are characteristic of direct invasion. With peribronchial infiltration there is reduction in size of the hemithorax, shifting of the trachea and mediastinum toward the lesion and ac-

centrated radiating striations from the lung root. Individual increases in the width or density of these shadows may produce triangles at the lung root with the apex pointing peripherally or broad bands extending into the lung field. In the latter there is danger of misinterpretation as "interlobar plastic pleurisy", but the multiplicity of radiations of lesser importance, found in cases of infiltrating new growth, should prevent the commission of this error.

In all cases, elevation of the diaphragm on the affected side, and particularly progressive elevation as revealed by serial x ray films is significant.

Bronchial Obstructive Group

In this group are found the usual signs of complete or partial atelectasis of a lobe or part of a lobe. This process may be solitary or it may be associated with a suppurative necrosis or a simple degeneration in the cancer tissue, producing cavitation. Either of these complications to a fixed lobar atelectasis is sufficiently typical to permit of accurate interpretation to the experienced eye. When however, the atelectasis is incomplete, the differentiation becomes more difficult and the lesion might easily be mistaken for a chronic localized inflammation of the lung. Three possible diagnoses emerge under these circumstances pulmonary tuberculosis, pulmonary suppuration (including foreign body as an exciting cause) and new growth.

Tuberculosis can be ruled out by the history, the absence of tubercle bacilli in the sputum and the relative indemnity of the remainder of the hemilateral and the totality of the contralateral lung fields.

From chronic suppuration the differentiation is not so easy. In distribution, however these lesions tend to be limited by anatomical boundaries lobule or lobe while the extent of the shadow of new growth is characteristically self limited (within the lobe). In chronic suppurative processes, where atelectasis and inflammation begin together, the pleura is generally involved before any extensive degree of shrinkage has taken place. Adhesions form between the parietal and visceral layers and the subsequent loss of volume of the involved lobe drags its content away from the level of these attachments. In new growth of the bronchus on the other hand, where atelectasis precedes or may remain free of inflammatory complications, pleural adhesions occur late and offer no mechanical impediment to the uniform shrinkage of the lobe. This is most easily detectable on the right side where shifting of the interlobar fissure is one of the striking accompaniments of these conditions. The x ray film, in consequence, reveals this fissure carried upward or downward, in the direction of the lesion. In inflammations the peripheral end is retarded in movement, while in new growths the peripheral end

either moves with or advances beyond the remainder of the line. In other words inflammatory lesions are characterized by a convexity of the interlobar fissure in the direction of the shift, whereas new growth shows either a straight line or a concavity in the direction of the shift. This advance movement of the lateral end of the inferior border of the atelectatic shadow, in upper lobe tumors, has already been pointed out by Golden⁹.

It has also been claimed by certain authors, notably Santé¹⁰, that obstructive emphysema may occur in tumors of this class, if a suitable intrabronchial impediment to the movement of air is developed. In the opinion of the writer, however, this is not the case. Loss of volume of the involved lobe starts with the beginning of impaired drainage and before obstruction occurs, the lobe is so reduced in size by the chronic atelectatic and infiltrative process, that a check-valve mechanism could scarcely reinflate it, even to its normal size. No photographic record of this condition has, to this author's knowledge, appeared as yet in the literature.

A point of lesser importance but equally noteworthy, is the fact that in inflammatory lesions (including tuberculosis), cavitation in the midst of the circumscribed or mottled x-ray shadows produces sufficient rarefaction to bring the Haversian system of the bones into detailed relief within its contours. In bronchial carcinoma, however, the opacity of the surrounding lung is sufficiently great to obscure bone detail, even in the centre of the shadow of a cavity.

Centrifugal Expansive Group

In the peripheral zone the shadow of the tumor mass is probably round until some important structure is encountered. Unfortunately, due to the absence of well-defined signs and symptoms in the early stages, x-rays are not often taken before the pleura is involved. The shadow is then obscured by collateral infiltration, effusion or atelectasis. Not infrequently bone destruction has already taken place.

SPECIALIZED DIAGNOSTIC METHODS

Carcinoma of the bronchus is rapidly being placed in line with other malignant diseases, where an early diagnosis is only made by the alertness of a good clinician and roentgenologist who establish the indications for biopsy wherever possible.

Bronchoscopy

Undoubtedly among the specialized methods for the obtainment of biopsy material, bronchoscopy ranks first. In practically all growths of the central zone and in the majority of the middle zone group, tissue can be taken from the tumor on direct examination. When seen, they are generally far enough advanced to be cyanotic, fungating and ulcerated with a sec-

ondary, acute, localized bronchitis. In cases of complete or nearly complete obstruction, quantities of mucopurulent material mixed with blood are retained distal to the mass and expelled upon the restoration of patency to the bronchial lumen.

Occasionally the removal of a biopsy specimen may instigate hemorrhage of disturbing severity. This blood should be sucked out to prevent accumulation in the bronchus or flooding of the branches leading to other lobes or the opposite lung. It is rarely dangerous and can always be controlled. By passing the end of the tube beyond the site of the lesion, the escape of blood is stopped by pressure and if it recurs the bronchus may be packed by narrow tape, attached to a strong thread leading out of the patient's mouth, the whole being left in situ for an hour or two. At any rate, the operator should never retreat from the field at the sight of an unusual amount of blood, as a subsequent atelectasis with fever and prostration will almost certainly replace the customary amelioration of symptoms, which follows the opening of a bronchus and the draining of the involved lobe.

Even when the necessary pathological confirmation cannot be secured in this way, a number of typically characteristic and strongly positive observations may be made. The trachea is commonly shifted toward the lesion, its wall or the wall of a bronchus bulges into the lumen, there are rigidity and fixity both in respect to motility and mobility, and the mucous membrane, instead of presenting the normal corrugations corresponding to the cartilaginous rings, may be uniformly smooth and pale or dull, thick and lustreless.

Accurate as bronchoscopy may be in the majority of bronchial new growths, it has little or no value in tumors arising in the smaller branches or the parenchyma of the lung, 35 per cent of the cases in this series. Two years ago a well-known internist in this city asserted that he would rather allow his patient to die than to advise his submission to bronchoscopic examination. Happily the acquisition of improved technical methods by a continually increasing number of men has long since removed the justification for such paternally protective measures. Bronchoscopy can always be carried out safely, without pain, under local anesthesia and frequently leads to the discovery of a benign growth or an unsuspected foreign body, which can be removed with every prospect of complete cure. An early bronchoscopy with negative results is always better than a late one with positive findings, but a negative bronchoscopy simply means that one method of diagnosis has failed. Jackson and Jackson¹¹ in their latest edition of the masterly treatment of the subject of peroral endoscopy state, "It is now generally accepted

that the bronchoscope affords the only means of making an early and positive diagnosis of malignant disease of the bronchi and lungs." Perhaps this attitude should not be too greatly stressed, as the mistake of considering this method as the only reliable procedure is certain to retard the diagnosis of a number of cases on the basis of exclusion and to allow them to drag on to a hopeless consummation.

Pneumothorax and Thoracoscopy

Effusion into the pleural cavity is a common accompaniment of carcinoma of the bronchus. In the peripheral zone group it occurs as a direct result of invasion of the visceral pleura by the malignant cells. Under these circumstances diagnostic tap may produce a hemorrhagic liquid containing cells which are useful in diagnosis. A clear straw-colored effusion is, however, equally typical. In the middle zone group effusion in the early stages is more likely to be a part of the general picture of the complicating "pneumonia." A chest tap produces a clear liquid without blood or tumor cells. There may even be a spontaneous clearing of these collections, together with the subsidence of fever and other acute clinical symptoms when the bronchus is opened by accident or by design.

At the same time that a specimen of pleural fluid is taken for laboratory study a useful diagnostic move can be made by evacuating the entire content and replacing it with air. X rays taken following this procedure will show a density of the involved lobe, much greater than that seen in other clinical types of pleurisy with effusion. There is also revealed a marked reduction in the volume of the lobe and a corresponding emphysema of the remainder of the lung or a portion of the border of the tumor mass may be brought to light.

In the peripheral zone group, even when no fluid is present, a great deal of information may be gleaned by creating a pneumothorax and inspecting the pleural cavity from inside by means of a thoracoscope. Although the author has attempted to do so on several occasions, he has never succeeded in obtaining biopsy material from the pleural surface of the lung. Adhesions are not always present at the site of the tumor even when it is near the surface.¹² If the patient is seen early enough this procedure should be a practical possibility in a limited number of cases without danger of traumatic collapse of the lung. At the same time secondary characteristics, corresponding in importance to those seen in bronchoscopy, may be observed. The pleura is lustreless and boggy in appearance over the affected lobe. There is a reduction in mobility of the lung, increasing to complete fixity as the pleural attachments are approached. The cardiac impulse instead of being transmitted by

the normal wave like fluctuation of the lung surface, becomes a massive rise and fall of diminished amplitude in the involved lobe. At the site of attachment between the two pleural layers, the string and band adhesions of an inflammatory process are absent and a circular fusion on a broad base is seen. The angle between the two pleural layers at the line of approximation instead of being acute as in inflammatory processes is rounded out by the spread of the malignant cells.

In cases where tumor tissue cannot be obtained the thoracoscope may also be of considerable assistance in judging the operability of the case. It may also assist in localization for the next procedure either by transillumination of the chest wall or by the guidance under direct observation of the end of an exploring needle inside the pleural cavity.

Punch Biopsy

When the tumor has been accurately localized by x ray or thoracoscopy or both, a biopsy trocar can be inserted directly into the mass for the taking of tissue. Crossing free pleural space should be avoided. Even the peripherally located growths are surrounded by an area of impaired drainage and retained infection. The danger of empyema is obvious.

Operative Biopsy

In the experience of the writer, metastatic glands, especially in the neck and axilla, are found more frequently in the peripheral zone group than in those more centrally located and always it would appear after the pleura has been reached and infiltrated.

In one case of this series where the diagnosis was in doubt and where biopsy tissue could not be obtained there was an associated pulmonary suppuration. In this instance a two-stage operation was deliberately done with the object of draining the abscess and at the same time of removing tissue for pathological examination. Naturally the possibility of a chronically draining malignant sinus was visualized. The patient was immediately placed under deep x ray therapy when the diagnosis was established and the sinus closed with surprising rapidity. The question is therefore left open as to how frequently this method should be used.

Bronchography

The injection of opaque substances into the bronchial tree can be carried out as an office procedure. It may show obstruction, stricture or deformity of the bronchial or tracheal lumen. In this way the necessity for bronchoscopy may be graphically demonstrated to the patient or his responsible associates. It should never be used as a substitute for bronchoscopy. The author has never used this method of examination in the bronchiectatic type of tumor and cannot therefore speak of its value.

DIFFERENTIAL DIAGNOSIS

The author willingly subscribes to the protean manifestations of this disease and to the many difficulties to be overcome before an accurate diagnosis can be made. He believes, however, that the disease can be diagnosed always in its early stages if the observer will train himself to be clinically sensitive to certain well-defined criteria. These may be individual and pathognomonic or inter-related and "atypical" but nevertheless indicating the next step in diagnostic procedure. Most of the errors, both of diagnosis and differential diagnosis, can be avoided by observing the following rules.

Substernal pain is nearly always a sign of important disease and demands thorough investigation.

A chronic cough with pain or dyspnea or both is rarely tuberculosis and should never be so diagnosed unless proved by repeated positive sputum examinations.

A constant chest pain should arrest attention and vagaries in chest pain demand immediate clarification.

In cases of pain in the shoulder extending up the neck or down the arm, look for Horner's syndrome, venous stasis, hoarseness, dysphagia.

"Unresolved pneumonia" is not a diagnosis and frequently masks cancer of the bronchus.

An apparent recovery from an "atypical" pneumonia does not rule out cancer of the bronchus.

Hemoptysis where the x-ray is negative or indefinite is an indication for bronchoscopy (suspected aneurysm excepted).

Diminished respiratory movement or diaphragmatic excursion if unilateral and not part of a clearly defined clinical entity is an indication for x-ray study.

Asthmatoid wheeze or after breathing are diagnostic of bronchial obstruction and are indications for bronchoscopy.

Unilateral bronchitis or unilateral asthma are indications for x-ray and bronchoscopic study.

A negative bronchoscopy, or the finding of tubercle bacilli in the sputum, does not rule out cancer of the bronchus.

Diminution in size of a hemithorax or shifting of the interlobar fissure with concavity toward the lesion is highly suspicious of carcinoma of the bronchus.

Elevation of a diaphragmatic dome, especially progressive elevation, is worthy of wide investigation.

SUMMARY

An analysis of the observations made on twenty-eight cases of primary carcinoma of the lung and three cases of pathologic diagnostic error are presented.

A classification is offered of three groups,

which, in the author's opinion, demonstrate a logical and serviceable interrelation between the anatomical situation and the clinical expression of the disease, and under these group headings the signs and symptoms are presented in an attempt to delineate definite clinical syndromes.

In order to maintain simplicity, the rarer forms, e.g., miliary carcinosis, bronchiectatic carcinoma and those with remote metastases have not been brought into the discussion. With the same purpose symptoms of a pulmonary arthropathic nature, directing attention to the inflammatory lung complication rather than the primary disease, such as, clubbing of the fingers and rheumatoid manifestations, are excluded from the typical clinical pictures. Discussion is likewise limited intentionally, to the early clinical findings in each group, wherever the later clinical features might cause confusion by overlapping with another group.

The application of the different technical methods which may be serviceable in diagnosis is discussed.

ANALYSIS OF CASE REPORTS

Of the thirty-one cases upon which this paper is based twenty-eight ran a typically malignant course and three cases although diagnosed carcinoma by examination of material obtained at biopsy through the bronchoscope, ran, subsequently, a benign course.

The malignant cases were all white males of the average age of forty-five years, the youngest thirty-six years and the oldest sixty-eight years. The occupations varied greatly and apparently had nothing to do with the etiology of the condition. Of these cases twenty-five are now dead and the remaining three are rapidly approaching death. Of the twenty-five who died, twenty-four lived for one year or less after the diagnosis was made. One case lived for two years and it is worthy of note that he was among those who received no treatment curatively intended.

Erythrocytopenia and leukocytosis were characteristic. The average red cell count was 4,106,000 per cu mm and the average white cell count was 14,900 per cu mm. The increase in white cells appeared to be associated with pulmonary inflammatory complications.

Bronchoscopy proved to be the most useful diagnostic method. Seven cases were not bronchoscoped because of the patients' poor clinical condition, metastases to the brain or the bones of the neck or shoulder, or because the tumor was so near the periphery of the lung that no purpose could be served. In the remaining twenty-four cases, satisfactory biopsy material was obtained in seventeen. Tissue obtained from the remaining seven cases was reported normal in five, chondroma in one and fibrotic nodule in one. It must be credited to the value of bron-

choscopy, that in two fatal cases, where no malignant tissue was found microscopically, definite secondary, intrabronchial, malignant characteristics could be observed and in three cases where microscopic evidence of malignancy was seen, but the subsequent course was benign, the bronchoscopic diagnosis was, congenital web of the bronchus, papilloma of the bronchus and fibrochondroma of the bronchus.

In view of these observations the author feels that a shadow of doubt is cast over the accuracy of previously reported cases of malignant disease of the bronchus "cured" by removal through the bronchoscope. The latter three cases have now been under observation for periods of from three and a half to four and a half years and it is difficult to believe that the mere removal of tissue from within a bronchus, or even the removal of a pedunculated growth, could completely eradicate a true carcinoma. It is much more logical to assume that carcinoma of the bronchus may fall into the category of growths such as appear in the urinary bladder, where the establishment of the grade or even the existence of malignancy is known to present insuperable difficulties on some occasions. Similarly, in spite of the death-dealing qualities of the average cancer of the bronchus, the possibility of malignant potentialities making a delayed appearance in an apparently benign growth, cannot be entirely denied. In this series, two cases suffered from cough, loss of weight and occasional hemoptysis, over a period of eight years prior to their last illness, according to the onset given in their personal history. In both of these cases, however, death followed within six months of the occurrence of symptoms leading to the diagnosis of cancer of the bronchus. The question whether such tumors do or do not exist can only be answered by repeated bronchoscopic and biopsy examinations of suspected cases over long periods of time. A check up of this kind was pursued for a period of three years in the three cases brought into question above, but in each instance the diagnosis was finally reversed.

Subdivided according to location, one tumor arose from the trachea to the right of the bifur-

cation, nineteen were in the right lung and eleven in the left. There were of the Hilus Infiltrating Group, five cases, Bronchial Obstructive Group, twenty cases (seventeen malignant—three benign), and Centrifugal Expansive Group, six cases.

In the single instance of tumor arising from the trachea the first symptom was dysphagia due to infiltration of the wall of the esophagus.

All cases in the peripheral zone showed involvement of the pleura and chest wall. In three instances destruction of bone had already occurred. One of these patients exhibited a definite "Pancoast Syndrome" of "Superior Pulmonary Sulcus Tumor." So distinctive, indeed, is the clinic of this type of tumor that it almost isolates itself and defies classification with other tumors of the lung.

The author is indebted to a number of his medical colleagues for assistance in many ways. To assign credit to them individually would be impractical. He especially desires however to mention the names of Dr. L. T. Perrault and Dr. R. F. Harlow for assistance in the collection of clinical data and to Dr. W. E. Youland of the Flower Hospital for a critical review of the pathological material.

words of mine are being taken down, and I hope that they will be published in the transactions, because at the end of the next fifty years, I shall be quite curious to see if my prophecy came true

PRESIDENT LORD It gives me the greatest of pleasure to call next upon Dr Frank E Kittredge of Nashua

DR FRANK E KITTREDGE *Mr President, and Gentlemen of the Society*—I have not Dr Flanders' wit, and I shall make no attempt at a speech, but I want my young friends, particularly the young men around Nashua who do work such as I do, not to think for a moment that fifty years of practice in medicine or of receiving honorable mention places me upon the shelf As Dr Flanders has said, I believe that I have practiced medicine during the best medical period in history I think that the doctors during the past fifty years have been more interested, have been able to do their work with a greater degree of comfort than they ever will be in the future

Now, if there are those among you who ever will stand where I am now standing, or who have practiced medicine for the greater number of fifty years, and who have received as much satisfaction and as much fun out of the practice of their profession as I have received out of practice, you certainly can rest assured that you made no mistake in the choice of your calling

PRESIDENT LORD I hate to voice this suspicion, but I think that a little detective work would reveal, in reference to the last two speakers, that somebody has been tinkering with the birth certificate records

I am going to ask if Dr Frank S Lovering of Moultonboro is here

[There was no response]

Is Dr William S Manuel of Portsmouth here?

[There was no response]

Is Dr Edward E Twombly of Colebrook here?

[There was no response]

These three men have also been in the practice of medicine for fifty years

I will ask, now, if Dr Ellen A Wallace of Manchester is here

DR ELLEN A WALLACE *Mr President and Gentlemen of the Society*—Fifty-three years ago, when I decided to be a doctor, all my family and my friends opposed it, because my health was not good and they said that I would never live to be a doctor Since I heard from Dr Metcalf that my fifty years was over, I have wished some of those people could know

that I had practiced medicine for fifty years [Dr Clifton S Abbott then assumed the Chairmanship of the Session]

CHAIRMAN ABBOTT Members of the New Hampshire Medical Society, you are now witnessing the high spot in the career of the Vice-President of your Society So far as I know, this is the only official duty that the Vice-President has But this, unfortunately for the Vice-President, has not escaped the eagle eye of our President or that of our Secretary, both of whom say, "No more will there be a year of delightful indolence for the Vice-President, for next year the Vice-President must have a job"

This being so, I will proceed with my job, and present to you the President of the New Hampshire Medical Society, Dr Frederic P Lord, who will deliver the President's Address

The President's Address was followed by a symposium on Obstetrics with the following speakers

Ante-Partum Care—Marion F Eades, Boston, Mass

Mechanics of Delivery (especially as it relates to intracranial hemorrhage)—Frederick C Irving, Boston, Mass

Post-Partum Infections—Foster S Kellogg, Boston, Mass

Care of the Newborn Infant—Richard S Eustis, Boston, Mass

Open discussion

WEDNESDAY MORNING, MAY 8, 1935

The Session convened at ten-fifty o'clock in the morning, with President Lord presiding

PRESIDENT LORD The meeting will please come to order

We have been entertaining angels for the last two days, mostly from New England, and, as their wings are not visible, I am going to ask them to stand as I call their names, and then, as each one wishes to say a word, I will be glad to hear from them These men are none other than the visiting delegates

Is Dr Charles Kinghorn from Kittery, Maine, here?

Is Dr Pillsbury of Lowell present, or Dr Dutton of Wakefield?

[Dr Dutton arose and the audience applauded.]

PRESIDENT LORD Is Dr Cutter of Providence here?

DR CUTTER *Mr President and Members of the New Hampshire Medical Society*—My colleague here says that I am the senior member, and I am very glad to bring the greetings of the Rhode Island Medical Society to this meeting of the New Hampshire Medical Society

It has been a very enjoyable meeting, and I have had a great deal of pleasure in listening to the program thus far. Our Society and our State organization are probably very similar to yours. We have the same problems to meet that you have, and we have the same threatening of industrial or state medicine that seems to be hanging over the rest of New England. I don't know when it is coming, but we have some indications of it at the present time.

Our treatment and care of the indigent patients, or the patients who are on relief, emergency relief, now have been delegated to the general profession in Providence. Instead of having city physicians or special physicians appointed to attend these patients they are allowed to call any physician in the community and that physician, if he gets an authorization from the Public Aid Department, can render a bill for fifty per cent of the normal ordinary fee which is charged. If the case is properly on relief, that bill will be paid, otherwise the physician is out of luck, as he frequently is.

The number of those cases, of course, and the number of cases that are entirely charity cases in our city, is very large indeed so that our income as physicians has been greatly curtailed, while the amount of work that we are doing has been perhaps up to par or a little better, but a large part of it has been and has to be charity work. People are not allowed to suffer, and we are not always able to discriminate between patients who will pay and the patients who will be entirely charity cases.

All the members of the profession in Rhode Island, I think, have been fairly busy. Their incomes have all been cut. I know that the income tax that we are paying as physicians is about fifty per cent of what it was six or seven years ago, and I presume that is true all over New England. The earned income that we receive is very much curtailed. And some of us find that as we are getting older, our work is also decreasing. I know, for myself, that for the past year or two my work has consisted very largely in signing death certificates.

PRESIDENT LORD Thank you, Dr. Cutter. We appreciate your remarks about Providence.

Is Dr. Philip Batchelder of Providence here this morning?

DR. PHILIP BATCHELDER I join with Dr. Cutter in bringing the greetings of the Rhode Island Medical Society. I am enjoying the meeting very much, too.

PRESIDENT LORD Our representative from Connecticut who I hope, is here, is Dr. Arthur B. Landry of Hartford, Connecticut.

DR. ARTHUR B. LANDRY Mr. President and members of the New Hampshire Medical So-

ciety—It is indeed a great pleasure for me to be here to represent the membership of the Connecticut State Medical Society.

I want to tell you that the State of Connecticut is celebrating its Tercentenary this year, and while I have not been delegated to invite you to come to our State and help us celebrate this great anniversary, I am going to do so just the same. I hope that as many of you who can come to Connecticut will do so.

The Connecticut State Medical Society holds a clinical congress in New Haven each year, and this year we hold the Congress in September. If you gentlemen can escape the fascinating influences of your medical centers for a while and can think of coming down to New Haven to this Clinical Congress, I am sure that you will be well entertained.

I want to thank you very much for the hand some way in which you have received us, and I hope that we will, accordingly, receive your delegates when they come to see us this month.

PRESIDENT LORD Is the delegate from Vermont here?

[There was no response.]

PRESIDENT LORD Are there any other visiting delegates present?

A MEMBER There is a gentleman here at my left, Mr. President, who informs me that he just arrived here by plane from Palo Alto, California, and tomorrow he is going to hop off again. He is Dr. Grooms of California.

DR. GROOMS I suppose it is rather a novelty for a medical man to travel much by plane. Since 1914, up to the present time, I think I have traveled something like 150,000 hours a year.

Traveling by air has its advantages and some disadvantages. I found out, too late, that you have a field here, otherwise, I would have landed on your doorstep instead of grounding at Boston. However, I hope that I will come this way again and I will make use of your local airport.

PRESIDENT LORD We hope you will, and we hope that others will try the same.

Our first presentation this morning will be on the subject of Bronchoscopy, given by Dr. John A. Coyle of Hanover and Dr. Leslie K. Sycamore of Hanover.

The morning program continued with the following two papers:

"Treatment of Burns," Grover C. Penberthy, Detroit, Michigan. Discussion opened by Walter H. Lacey, Keene, James W. Jameson, Concord.

"Nutritive Failures as a Clinical Problem," James S. McLester, Birmingham, Alabama, President Elect, American Medical Association.

WEDNESDAY AFTERNOON, MAY 8, 1935

The Session convened at three o'clock in the afternoon, with President Lord presiding

PRESIDENT LORD The meeting will please come to order

The first matter on the program this afternoon is slightly different from the usual order of things We are going to introduce our new President to the Society a little earlier than formerly

In his régime as Vice-President, as he says himself, he had "nothing to do", but we have now fixed it up so that in the future the President will have nothing to do because the Vice-President will do it all So it will work out that Dr Abbott has had nothing to do as Vice-President, and he will also have nothing to do as President He has been Secretary of his own county society, and we all know him very well and have known him for many years

I take great pleasure in presenting our new President, Dr Clifton S Abbott

PRESIDENT-ELECT ABBOTT My friends, I thank you for this fine reception and I thank you for this distinguished honor that you have done me by electing me your President I am beginning to realize that there are exacting duties, perplexing problems and considerable hard work associated with the office All that I can say at this time is that I hope, with your help, I may carry on as acceptably as some of my eminent predecessors in the past

PRESIDENT LORD Gentlemen, I wish you to listen to a man who will speak to us in regard to a matter in which we are all interested I will ask Lt Col John T Aydelotte if he will come to the platform

LT COL AYDELOTTE *Mr President and members of the New Hampshire Medical Society—*My message, happily, is brief It is an important message, nevertheless

It is my purpose to discuss one or two features of the present military medical preparedness of our country For a period after the war, we had many thousands of medical men who knew much about the art of war in a medical sense Those of you who were in the army know that you must be something more than a private practitioner in order, properly, to take care of such work

I believe that it may be properly said to be a truth that it is a little late to begin to learn after war is being declared For that reason, wise heads in our Federal Government believed, fought for, and finally brought to pass a law which would continue the knowledge gained in war Among other methods, there was established what was known as an R O T C unit in the principal medical schools Schools in every portion of America were represented with

R O T C units, in which medical students were taught military science, as it pertains to medicine, with their medical career

I know that those units were well received, and that the teaching was believed to be of value by the faculty We, ourselves, in the regular Army Medical Corps, were proud of what we were doing

The Congress, in recent years, has failed to appropriate money for the maintenance of these units As a consequence, the last one of our classes graduated members and commissioned them in 1935

How are we going to get replacements for the Reserve Corps of the Medical Department hereafter? Fifty per cent of our reservists commissioned in the Medical Department came from our medical units But that is lost to us now, and I would say that we are somewhat concerned as to where our replacements are to come from hereafter And it is not sufficient to say "replacements" only, for we not only require replacements, gentlemen, but actually, we require additions The only thing that we can do is to come to the medical profession of the country And so, we come out and tell our story to you

What am I asking you to do about it, gentlemen? Only this You must be preparedness-minded

Whom do we want? We want all physically fit medical, dental and veterinary men, that is true, but we must have the young fellows, too The older men have learned much, but after all, the older men are not going to be with us so long as the younger ones, and we would like to train the latter as soon after they leave the medical schools as possible

The trained men will certainly get a better berth They will get a better commission when war starts than the ones who will take potluck if they wait

Please advise the young men of the medical profession, then, that it behooves them, as a part of their duties, to be prepared in case of war I don't know how Mr Young Medical Man may feel about it now, when war is perhaps so remote But I do know this I know that many thousands of doctors came into the army during the war, and how much better for every one of them who came in if they had had some training before the day arrived when they were to put on their uniforms

PRESIDENT LORD There is a sentence in our By-Laws to this effect, concerning the duties of the Committee on Public Relations, Public Policy and Legislation, now changed to the Committee on Public Relations, that it shall have the authority to be heard before the entire Society upon questions of great concern at such time as may be arranged during the annual session

This committee feels that this is an occasion where we wish to have presented to you a matter of great concern, and I am going to ask the Chairman of the Committee on Medical Relief to speak to us to-day.

Dr. ROBERT J. GRAVES *Mr President and Gentlemen*—The basis for the work of the Advisory Committee on Medical Relief are two fundamental premises, the first of which is that the patient shall have an opportunity within reasonable limits, of selecting his own doctor, and the second of which is that the doctor shall receive a reasonable remuneration for his services.

Probably the shortest way of getting across what we have done to date, which is tentative but reasonably final, will be to read our report which we made to the House of Delegates.

[Dr Graves then read the report referred to.]

PRESIDENT LORD In arranging this program, the Committee was very anxious to have some discussion in regard to medical economics, in which we are all interested.

Perhaps the trouble is that too many of us would like to talk about it. So we have gone to the one who could tell us more authoritatively about it than any one I know.

It is a great pleasure for me to present to you at this time Dr Nathan B. Van Eetten of New York City, Vice Speaker of the House of Delegates of the American Medical Association who will address you on the subject of "Medical Economics of 1935."

The program continued as follows

"Bright's Disease," Harold E. MacMahon Boston, Mass. Discussion opened by A. Philip LaFrance, Laconia, Clarence O. Coburn Manchester.

"Treatment of Skull Fractures," Harry E. Mook, Chicago, Illinois. Discussion opened by Emery M. Fitch, Claremont, Herbert L. Taylor, Portsmouth.

REPORT OF THE TRUSTEES OF THE NEW HAMPSHIRE MEDICAL SOCIETY

For the Year Ending May 1 1935

RECEIPTS

December 26 1934—Received from Carylton R. Metcalf Treasurer. This was deposited in the Nashua Trust Company as a part of the General Fund. \$500.00

EXPENDITURES

August 27 1934—Paid D. G. Smith Delegate to the A. M. A., his expenses for the Cleveland meeting by check from the Portsmouth Trust and Guarantee Company. \$81.02

SPECIAL FUNDS

The Bartlett Fund

Deposit in the Portsmouth Savings Bank—Book No. 21110. The original bequest (\$352.11) by the terms of the will is kept as a permanent fund. \$5 645.22

The Pray Fund

Deposit in the Strafford Savings Bank—Book No. A 42. \$1000.00 of this must be kept as a permanent fund the income of which is to be expended for prize essays. 1 357.95

The Burnham Fund

Deposit in the New Hampshire Savings Bank—Book No. 80100. \$1,140.00 must be kept permanently the income to be expended for prize essays. \$100.04 was withdrawn for this use in 1934. 1 964.12

The Benevolence Fund

Deposit in the New Hampshire Savings Bank—Book No. 99559. 902.09

The General Fund

Deposit in the Portsmouth Trust & Guarantee Company—Book No. 12813. 3 078.61

Deposit in the New Hampshire Savings Bank—Book No. 35698. 4 938.44

Deposit in the Nashua Trust Company Savings Department—Book No. 4882. 500.00

Total Funds on Deposit. \$18 386.43

FUNDS NOT FOR GENERAL USE

The Bartlett Fund. \$352.11
The Pray Fund. 1 357.95
The Burnham Fund. 1 964.12
The Benevolence Fund. 902.09
4 576.27

Present Funds Available for General Use. \$13 810.16

Funds Available for General Use May 1 1934. 13 035.64

Net Gain for the Year. \$774.52

The balance due the Society from the Merrimack River Savings Bank—Book No. 28934—in process of liquidation is \$733.55
Your Trustees consider this of little value.

The Accounts of the Treasurer have been examined and found correctly cast and properly vouched.

HENRY O. SMITH
THOMAS W. LUCE.

PRESIDENT LORD If there is no further business to come before the meeting, I declare this One Hundred and Forty Fourth Annual Session of the New Hampshire Medical Society adjourned.

MISCELLANY

EXCERPT FROM VITAL STATISTICS
OF NEW HAMPSHIRE

During the year 1933 there were 7,419 births, 6,304 marriages and 6,498 deaths, while during 1934 there were 7,864 births, 7,261 marriages and 6,398 deaths. This makes an increase of 445 births and 957 marriages during the year 1934, while there was a decrease of 100 deaths.

During the year 1933 there were 615 divorces (legal separations and annulments included), while during 1934 there were 737. There were 545 minor children affected by the divorces for the year 1933, while for the year 1934 there were 696 children affected.—*Health* Issued monthly by the New Hampshire Board of Health.

RECENT DEATHS

REMICK—EDWIN REMICK, M.D., of Tamworth, New Hampshire, died suddenly, June 2, 1935. He was born in Tamworth, New Hampshire, in 1866, the son of Levi and Harriet Beede Remick, and was educated in the public schools, Fryeburg and Northwood Academies and was graduated from the University of Vermont Medical School in 1894.

He was a member of Carroll County Medical Society, the New Hampshire Medical Society, and the American Medical Association.

Dr Remick is succeeded by his son, Dr Edwin C Remick, of Tamworth.

MOUSLEY—BAYARD TAYLOR MOUSLEY, M.D., of Walpole, New Hampshire, died at his home, May 30, 1935. He was born in Oxford, New Hampshire, January 17, 1879, the son of the late William and Catherine Quint Mousley.

He graduated from the Kimball Union Academy at Meriden, studied two years at the University of Vermont and obtained his degree in medicine at the University of Maryland.

FELLOWS—GEORGE ROBERT FELLOWS, M.D., of Seabrook, New Hampshire, died late in June 1935, aged eighty six years. He had practiced in Seabrook for forty-nine years and was in Florida where he went in an effort to regain his health.

The announcement from Florida was dated June 28, but without specific statement of the date of death. He is believed to have been the oldest practitioner of New Hampshire.

Dr Fellows was a member of the New Hampshire Medical Society.

COMBINED EXTRA-UTERINE AND INTRA-UTERINE
PREGNANCY*

A Report of Two Cases

BY ROY J HEFFERNAN, M.D.†

CO-EXISTING extra-uterine and intra-uterine pregnancy is unusual but not extremely rare. Nengebauer¹ collected 243 cases from the literature up to 1913. Stein² added 36 cases more up to 1928, including one of his own. A fairly comprehensive search revealed no further cases. Thus the instances described below make the total number reported to date, 281.

CASE 1 Mrs J, aged twenty five, family and past history unimportant, no previous pregnancies. The last regular period occurred June 12. On July 23, the patient began flowing and developed sharp pains in the right lower quadrant. Her family doctor performed a curettage at home on August 7. The flowing and pains continued intermittently, with dizziness and syncope. On August 22, I was asked to see the patient and found her resting comfortably in bed with a normal temperature, a pulse rate of 112 and a respiratory rate of 24. The complaints were low abdominal discomfort with pain on sitting or attempt at defecation. Physical examination revealed pallor of the skin and mucous membranes. A tender mass, more prominent on the right, extended to the level of the umbilicus. Vaginal examination showed a nulliparous introitus, with slight bloody discharge. The cervix was closed and cer-

vical tug was very painful. The fundus seemed displaced to the left but could not be definitely outlined. The patient was transferred to St. Margaret's Hospital, Dorchester, with a diagnosis of ruptured extra uterine pregnancy.

On August 23, under gas ether anesthesia the abdomen was opened by a median suprapubic incision, exposing a hematocele which filled the right side of the pelvis. The clots and fluid blood were removed disclosing a rupture of the outer third of the right tube. The uterus was about twice normal size, the right ovary and left adnexa appeared normal. After a right salpingectomy, the abdomen was closed in layers without drainage.

Seventeen months later I delivered this patient, by low forceps, of a full term normal female child.

Eight months later the patient informed me, by telephone, that she had missed two periods, had begun to flow one hour before and had severe pain in her lower left abdomen. She said "I think my left tube is bursting now!"

Examination showed a moderate bloody flow, a uterus enlarged to the size of a ten weeks' pregnancy, with the fundus in good anterior position. There was general pelvic tenderness most marked in the left vault, which contained a lemon sized tender mass. The patient was transferred to the Carney Hospital and prepared for immediate operation.

The abdomen was reopened in the median line disclosing considerable free blood and clots with a break of the middle third of the left tube, which contained a ruptured vessel, pumping blood. It was remarked that the uterus appeared larger than usual.

*Read at a meeting of the Obstetrical Society of Boston February 19, 1935.

for a tubal pregnancy. A left salpingectomy was done, the blood clots were removed but the fluid blood was undisturbed. The incision was then closed without drainage. As an intrauterine pregnancy was suspected the patient was kept under the influence of morphia for three days but on the fourth day after the operation the patient expelled a two months fetus with membranes intact. She made a good recovery and left the hospital on the thirteenth day.

CASE 2. Mrs. C., aged thirty four was seen in consultation with Dr. Francis Broderick of Jamaica Plain on March 24 at the Forest Hills Hospital. The past history and family history were irrelevant. There had been one miscarriage four years previously and one full term normal delivery fourteen months ago. In January there had been one scant period the first since delivery but the patient thought her amenorrhea was due to the fact that she was still nursing the baby.

On March 23 while tugging at the baby carriage she felt a sudden, severe pain in the right lower abdomen. Thinking she had strained a muscle the patient went to bed but the pain became more severe and she was sent to the hospital.

Examination showed extreme pallor a pulse of 148 and the blood pressure 60 over 0. The abdomen was moderately distended with marked tenderness in the right lower quadrant. Vaginal examination revealed a parous introitus with no signs of inflammation and no bloody discharge. The cervix was closed and cervical tug very painful. The fundus was enlarged but definite palpation was impossible because of pelvic tenderness. An indefinite tender mass could be felt in the right vault.

Glucose and salt solution were given by vein and

hypodermoclysis. A donor was secured and 750 cc. of blood were given by the citrate method. The pulse dropped to 112 and the patient's general condition was very much improved. Under local anesthesia supplemented later with nitrous oxide and oxygen the abdomen was opened by a median suprapubic incision. The peritoneal cavity contained a tremendous amount of fluid and clotted blood. The distal half of the right tube was ruptured. This was quickly removed and all easily accessible clots were extracted. The incision was closed without drainage and the patient returned to bed in fair condition pulse 114 blood pressure 94 over 48.

Three days later, with very little flowing the patient expelled a ten weeks fetus promptly followed by placenta and membranes. After an afebrile convalescence the patient left the hospital on the fifteenth day and soon regained her normal health.

SUMMARY

Two cases of combined extra uterine and intra uterine pregnancy are described, bringing the total number reported to date up to 281.

Clinically the condition should be borne in mind lest the passage of conception products per vaginam lull one into a false sense of security concerning extra uterine pregnancy.

CASE REPORT BRONCHIAL ASTHMA DUE TO PAPER SENSITIVITY

BY THEODORE BENNETT, M.D.*

THE following case of asthmatic bronchitis is reported because of its unusual etiology and its subsequent cure, upon the discovery and removal of the irritating cause.

I. S. a white female aged ten, was first seen by me in August, 1931 with a history of attacks of difficulty in breathing occurring at irregular periods for the past six years. The attacks would occur suddenly were accompanied by expiratory dyspnea and considerable wheezing and would last from a day to as long as one week. They were relieved temporarily by the administration of either adrenalin or ephedrine sulphate and in the more prolonged attacks by the use of morphine.

Skin tests performed by competent allergists for the routine foreign proteins were all negative.

Past history revealed the fact that shortly before the onset of the asthma the patient had had pertussis followed by pneumonia. The family history disclosed a definite history of allergy the mother having hay fever and a younger sister having occasional attacks of urticaria.

During the month of August the patient had three asthmatic attacks and on discussing the case further with the mother the following information was obtained namely that in infancy the patient developed the habit, which has persisted up to the present time, of eating paper of all descriptions. As she became older the habit became so entrenched that

in spite of the most severe and arduous supervision the family was unable to bring about its correction. A skin test for paper showed a marked reaction and instructions were given to the mother in an attempt to remove this irritating habit.

The patient was not seen again until April of 1934 when she was brought to me because of loss of weight, persistent cough and night sweats. An interval history disclosed the fact that she had been sent away to a foster home as a problem child but in spite of strict supervision she still ate paper when excited resulting in an attack of asthma shortly thereafter. Examination at this time disclosed a marked degree of malnutrition and secondary anemia. Height, 57½ inches (2 inches shorter than average for age). Weight, 65 pounds. (17 pounds underweight). Tuberculosis was ruled out by a negative tuberculin 1:1000 and a negative x-ray of the lungs. With complete bed rest and high caloric diet the patient gained five pounds in two weeks but one week later after eating paper developed an attack of asthma.

Because of the direct relationship between the asthma and the eating of paper and because it was impossible to break this pernicious habit, she was referred for psychoanalysis in an attempt to find some cause for this peculiar mental aberration. After three months of this form of treatment (May to August) she stopped the habit and for five months has not had an attack of asthma.

The time is too short to state definitely that this patient is completely cured but the case is interesting from its etiological standpoint.

CASE 21291

PRESENTATION OF CASE

A fifty-eight year old Italian candy worker entered complaining of chest pain and afternoon fever

Eleven months before admission he had sudden onset of sharp pain in the anterior portion of the left upper chest. The pain was constant and not aggravated by deep breathing or exertion. It lasted for about three days and then completely disappeared. There was some associated cough with slight blood streaked sputum on two or three occasions but no frank hemoptysis. He remained in bed during this three day period, having an afternoon temperature of 99° to 100°, and then returned to work. He felt perfectly well although he began to lose weight and during the next seven months lost twenty-eight pounds. He still had some cough, worse in the morning, which he attributed to cigarettes. Four months before admission he noticed fever at night but no real night sweats. At about this time he began having a low grade fever of 99° to 100° every afternoon with a normal temperature in the morning. Two months before admission he had another attack of chest pain similar to the first which lasted only one day and this time was associated with more purulent and blood streaked sputum. As before there was no malaise and no relation to exertion or deep breathing. Several sputum specimens were sent to a laboratory and were reported as negative for tubercle bacilli. X-rays at this time were said to show pleurisy. He was put to bed however, and remained there during the past two months. He continued to have afternoon fever but felt strong and gained nine pounds during the past six weeks. Four weeks before admission he had a third attack of chest pain exactly similar to his previous attacks and again lasting three days. His sputum again was negative for tubercle bacilli and x-rays again were reported as having shown pleurisy in the left chest.

His family history is non-contributory.

He had been married thirty-two years. His wife and six children were living and well. One of his sons had had a tuberculous knee for four

years without, however, any evidence of pulmonary involvement.

He had influenza eight years before entry followed by acute nephritis and nocturia for the following three months. He had frequent sore throats and had had typhoid fever at the age of 20.

Physical examination showed a well-developed and nourished middle-aged man in no apparent distress. His teeth were dirty and there was moderate pyorrhea. The chest was barrel shaped and expansion was better on the right. The right lung was normal. The upper half of the left lung anteriorly showed flatness, absent tactile fremitus, diminished spoken voice and bronchial breathing. Posteriorly at the left base there was flatness, absent tactile fremitus and diminished breath sounds. There were fine râles at the angle of the left scapula and coarse râles just below the right scapula. Because of the flatness in the lung fields the left border of the heart could not be made out. No murmurs were heard. The blood pressure was 110/66.

The temperature was 98.4°, the pulse 100. The respirations were 20.

Examination of the urine showed a specific gravity of 1.010 to 1.025 and a "green with" test for sugar. The sediment was negative. The blood showed a red cell count of 4,470,000, with a hemoglobin of 90 per cent. The white cell count was 24,650, 84 per cent polymorphonuclears. The stools were negative. Six sputum examinations were negative for tubercle bacilli. A few were blood tinged. A Hinton test was positive, a Wassermann negative. The phenolsulphonephthalein test gave 65 per cent excretion in two hours, 20 per cent during the first fifteen minutes.

X-ray examination of the chest showed hazy homogeneous dullness involving the greater portion of the left lung field. There was only a small amount of radiant lung above the costophrenic angle. A lateral view showed that the dullness lay entirely anterior to the septum between the upper and lower lobes and was sharply limited by the septum. The diaphragm on the left was high in position and somewhat limited in excursion. The heart shadow and trachea were displaced to the left and there was narrowing of the interspaces on this side. The right lung field was clear. There was a 2 centimeter irregular area of calcification at the left lung root.

He continued to have a slightly elevated temperature in the afternoon and evening. On the ninth day a bronchoscopic examination showed a generalized thickening of the mucosa of the left bronchus. The left upper lobe bronchus was very definitely narrowed but there was no outcropping. A small amount of purulent secretion was seen coming out of this upper lobe bronchus.

The carina between the upper lobe bronchus and the main bronchus was thickened. The following day he was put on potassium iodide solution, 15 drops three times a day. An x-ray film following pneumothorax on the thirteenth day showed fluid in the left costophrenic angle. There was a questionable 3 centimeter cavity with a fluid level in the region of the collapsed lung field. This cavity could not be seen very well on a lateral film. The findings were consistent with an abscess cavity in the collapsed left upper lobe. The hanes in the chest showed no evidence of metastases. On the sixteenth day 100 cubic centimeters of turbid yellow fluid was removed from the left pleural cavity. The fluid showed a specific gravity of 1.030 and had a cell count of 10,000 per centimeter, 90 per cent lymphocytes and 10 per cent polymorphonuclears. A smear showed no tubercle bacilli. A guinea pig inoculated with this fluid died ten days after inoculation of a streptococcus infection.

Another film with the artificial pneumothorax showed that the fluid level previously described at the left base was still present and in addition there were several other ringlike shadows just above the fluid level at the left base. Re-examination two days later showed a shifting fluid level which in the anterior posterior view was at the left of the fourth left anterior inter space upon deep inspiration. In the right lateral anterior posterior view the fluid level occupied the pleural space of the diaphragm up to the axilla. He was discharged approximately three weeks after admission.

At home he managed fairly well for a month or so and then began suddenly to go downhill very rapidly. There were no particularly acute episodes and he died approximately three months after discharge from the hospital.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD D. CHURCHILL. The clinical course was that of a fifteen months' illness in the case of a fifty-eight year old Italian progressive except for one period when he gained six pounds in weight, and punctuated by hemoptysis, cough and pleuritic pain. I think we must take into consideration the fact that this man was perfectly well and then was affected by an illness of a total duration of fifteen months with a progressive downhill course terminating in death. There were many sputum examinations all of which are reported as negative for tubercle bacilli.

X RAY INTERPRETATION

DR. GEORGE W. HOLMES. This patient has had a large number of x-ray films taken, some of which were taken at this hospital, some in another institution. This is the first film that we have a record of and it shows a very definite

extensive lesion involving the right upper lobe. The film taken about two months later shows an extension of that process apparently beyond the upper lobe. The left lung is unusually clear and brilliant, probably some compensatory emphysema but certainly no evidence of disease in this lung. An interesting point is that in the first film the heart is visible to the right of the spine and in the later films is not. I think it is fair to assume with the other findings that there has been a decrease in volume of the lung during that period. These films also show a dense apparently calcified mass near the root of the right lung. It is present in most of the films taken.

This film is the first one taken after he arrived at the hospital and does not give us much additional information over the films that he already had. There is a little more penetration. It shows some of the structure of the involved area. Certainly at that time there was nothing we could interpret as cavity formation. There is moderate elevation of the diaphragm, displacement of the heart and trachea and some narrowing of the costal spaces due to a process which is apparently confined to the upper part of the right lung.

Here we have a lateral view of the chest taken. This line is due to the septum between the upper and middle lobes. The lower lobe is entirely free. The process is confined to the upper lobe.

This is the film taken after pneumothorax, showing the partially collapsed lung, a moderate amount of fluid in the chest and in that area of pneumothorax, dense adhesions—shadows which I interpret as adhesions—extending from the lung to the pleura.

This film was taken about a month after admission. You can see a definite fluid level here. You might question whether that was in the lung or pleura. This is an antero-posterior view with the patient lying on his side. It shows the fluid level.

DR. CHURCHILL. Will you commit yourself definitely as to the fluid level being in a cavity within the lung or in the pleura?

DR. HOLMES. Of course the point that Dr. Churchill just made is a very important one. My experience has been that cavities like this with fluid in them are very rare in the pleural space. Just on the chances I would put it in the lung. But in this film it looks as if the fluid level went beyond the edge of the lung. That is the edge of the collapsed lung. I think it could perfectly well be in the lung. It hardly seems likely, that with the pleural space involved it would be possible to have as much collapse as that or such a fluid shift as you get here. I think you can say he has a cavity in the lung.

DR. CHURCHILL. Is this mediastinal shadow the aorta?

DR HOLMES I think so. One represents the ascending portion, the other the descending. I would not expect to find anything particularly wrong with the heart or aorta. I do not believe there is anything more. I think this calcified gland would influence me somewhat in the interpretation of the findings. We do not get calcification in tumors as a rule. Then too, I think it is rare for calcification to occur in metastatic glands. Is it not, Dr Mallory?

DR TRACY B MALLORY Yes, I should say so.

DR CHURCHILL In reviewing this first film taken on admission, there are a few points of interest. A note was made on physical examination that the left border could not be determined because of flatness in the left chest anteriorly. When it is impossible to percuss the left border of the heart, very definite evidence can be obtained about displacement of the mediastinum by palpation of the trachea. Judging from the x-ray film the trachea would have been definitely felt to the left and a clinical diagnosis then could have been made of a lesion in the lung with displacement of the mediastinum toward the affected side. The suspicion of the examiner would then be aroused that the flatness was not due to fluid but to collapsed lung.

The physical signs as given stated that there was bronchial breathing anteriorly in this portion of the collapsed lung. If that is a true observation we must postulate an open bronchus rather than a closed bronchus. On the other hand, with marked displacement of the trachea, it is quite easy in placing the stethoscope anteriorly to receive direct transmission of the tracheal breath sounds. The x-ray at this time, as Dr Holmes said, shows diffuse opacity associated with displacement of the mediastinum toward the left. There is no evidence of mass or of parenchymatous lung disease.

As to the cavity that appeared after the pneumothorax, I am uneasy about its interpretation. In the presence of pleural effusion and in the presence of effusion plus air in the pleural cavity, I think Dr Holmes is right in being conservative about definitely placing that shadow within the lung. We have had a good deal of experience in cases of empyema with shadows that look for all the world like cavitation in the lung with fluid levels, and yet the clinical courses of the patients seem to indicate that the disease is confined to the pleura. Although Dr Holmes is inclined to lean toward cavitation in the lung, I should lean toward its being a recess of the pleura with a fluid level from the effusion. The calcification at the hilum raises the question of tuberculosis. And even after the many sputum examinations I do not think that tuberculosis can be definitely ruled out in this patient. Tuberculosis in one lung, however, will rarely pro-

duce a steadily downhill course and death within fifteen months in a man of this age, particularly with a negative sputum throughout and with the slight febrile and general disturbance that he has shown.

I can see no other diagnosis on the data available than a progressive malignant lesion primary in the left lung. The fact that this was not shown by bronchoscopy does not exclude that diagnosis because bronchoscopy is limited in its ability to confirm the diagnosis of carcinoma of the lung. If it is positive it is accurate, if it is negative it may mean very little. The physical signs at the left base at the time he came in were interesting because they were those of a high diaphragm and there is no record of fluoroscopic findings which state that the diaphragm was high and limited in excursion and it was not stated whether the motion was paradoxical. Carcinoma of the lung may produce paralysis of the diaphragm by direct invasion of the phrenic nerve. This is one possible interpretation of the high diaphragm. The other interpretation is that the atelectasis increased the negative intrathoracic pressure giving a high and relatively fixed diaphragm. In conclusion, although I am not entirely willing to rule out tuberculosis, I can make no other diagnosis than a progressive primary carcinoma of the left lung.

CLINICAL DISCUSSION

DR DONALD S KING My reaction on this case illustrates well the danger of a new idea. I have been impressed with the frequency with which the bronchi are involved in pulmonary tuberculosis. We have seen a number of cases where the atelectasis was definitely due to stenosis of the bronchi from tuberculous infection. In this particular case I studied the early film before atelectasis had taken place and thought that the process looked more like pulmonary tuberculosis than cancer. This diagnosis was made partly because of the calcified glands which were definitely present and partly because of the mottling in the upper lobe. The atelectasis which developed later I thought was due to tuberculosis of the bronchi. I tried to sell the idea to Dr Cass but I never really convinced him that the case was not one of cancer. He examined very carefully a large number of sputum specimens and could find no tubercle bacilli, and it was on the basis of these repeatedly negative sputums that he insisted the process could not be tuberculosis. I had a faint ray of hope when the autopsy was done because in the gross there did appear to be an area of active tuberculosis in the upper lobe as well as the obvious carcinoma, but I now understand that microscopic examination has ruled out tuberculosis and that the whole process was due to carcinoma.

CLINICAL DIAGNOSES

Pulmonary tuberculosis
Artificial pneumothorax
Pleural effusion

DR EDWARD D CHURCHILL'S DIAGNOSIS

Primary carcinoma of the lung

ANATOMIO DIAGNOSES

Carcinoma, epidermoid, bronchiogenic, left upper lobe
Pulmonary abscesses, multiple
Pleuritis, chronic fibrous
Empyema, left
Emphysema, right lung

PATHOLOGIO DISCUSSION

DR. MALLORY At autopsy we found a large tumor mass surrounding the branch of the left bronchus leading to the upper lobe. The mass seemed to be largely outside the bronchus and it was not evident in gross whether or not the mucosa was involved. I am not at all surprised that the bronchoscopist was unable to make a positive diagnosis because it was not until we had sections that we felt sure that the mucosa was involved and that the tumor was primary there. The bronchi of the upper lobe distal to the point of obstruction were dilated and filled with pus and well out in the periphery of the lobe were numerous abscess cavities. Other abscess cavities were found in the lower lobe, some of them quite definitely within the lung others lying between the lung and the pleural cavity so that it was rather difficult to know whether to classify them as empyema or as lung abscesses. My impression was that although practically all of them started as lung abscesses several of them had broken through into the pleural cavity. The pleura itself was enormously thickened at the time of autopsy. That thickening must have developed in the course of the disease, since he first came under observation because at autopsy the pleura was everywhere from five millimeters to one centimeter in thickness and was as dense as cartilage. It would have been rather difficult to get any x ray picture through it at all.

The pericardium showed a fairly fresh pericarditis just beginning to undergo organization. We were not able, as Dr King told you to find any positive evidence of tuberculosis though at first one of the cavities at the apex seemed suggestive. Histologically, however, none of them showed tuberculosis and all proved to be purulent abscesses. The lymph nodes at the hilus were markedly anthracotic and fibrous but we did not find a calcified one.

CASE 21292

PRESENTATION OF CASE

A thirty two year old Canadian upholsterer entered complaining of fever and cough.

Eighteen days before entry he developed coryza and began to sweat considerably at night. Six days later he began to have an unproductive cough and he visited his physician who gave him medicine. He then developed muscular soreness and marked chilly sensations while in bed. One week before entry he began to raise pink sputum which gradually became brown and increased in quantity. Three days before entry he complained of a "tight sensation" in the left lower and right upper chests but he had no real pleural pain with the cough or on breathing. There was no previous history of cough, sputum, hemoptysis, weight loss, night sweats or poor health.

He was married and had one child who was living and well. His wife was six months pregnant. There were no miscarriages.

Ten months before entry he had a slight attack of what was called "stomach ulcers", which responded to dietary treatment.

Physical examination showed a well-developed, emaciated, cyanotic man in marked respiratory distress, sweating profusely and coughing up small amounts of greenish slightly pink flecked, tenacious sputum. There were herpes under the nose and on the lips. Several teeth were missing. There was slight pyorrhea. His throat and tonsils were slightly injected. There was slight postnasal discharge. Rales were heard throughout both lungs. At the left base posteriorly there were dullness to flatness, bronchial breathing, increased tactile fremitus and whispered and spoken voice. Similar signs were found over the area corresponding to the right middle lobe. A friction rub was also heard at the left base. One examiner found amphoric breath sounds and slight tympany high in the right axilla and over the spine of the scapula. The heart was negative. The blood pressure was 130/50.

The temperature was 104.1°, the pulse 120. The respirations were 45.

Examination of the urine was negative except for an orange test for sugar. (He had been given intravenous glucose.) The blood showed a red cell count of 4,200,000, with a hemoglobin of 60 per cent. The white cell count was 34,500. 97 per cent polymorphonuclears. The sputum was thick, mucopurulent and contained numerous pneumococci, not types I, II or III. No tubercle bacilli were found. A blood culture showed no growth. A throat culture was negative for hemolytic streptococcus. A Hinton test was negative.

X ray examination of the chest showed complete dullness of the right lung field with the

exception of an area just above the diaphragm. There was also dullness in the middle part of the left lower lung field and mottled dullness in the left upper lung field. The heart was not displaced.

The morning after admission there was evidence of complete consolidation of the left lower and right middle lobes. He was put in an oxygen tent. On the fourth day he was given two liters of ten per cent glucose. The temperature ranged between 101° and 102° and the pulse between 120 and 135. The white blood cell count ranged between 30,000 and 60,000 with 95 per cent polymorphonuclears. An x-ray film on the ninth day showed that the dullness in the right upper lobe had become less dense while that in the region of the left lower and upper lobes was increased. On the eleventh day the sputum for the first time showed numerous acid fast bacilli. He went downhill fairly rapidly and died three weeks after admission, approximately five and a half weeks after the onset of his illness.

DIFFERENTIAL DIAGNOSIS

DR DONALD S KING The history of the present illness is that of an acute upper respiratory infection with pneumonia.

The physical examination is that of areas of consolidation in both lungs. So far we are not getting away from an acute respiratory infection.

The main thing in the laboratory notes is the high white cell count with the high percentage of polymorphonuclears.

"X-ray examination of the chest showed complete dullness of the right lung field with the exception of an area just above the diaphragm." That is an important finding in that it rules out empyema unless it is encapsulated.

X-RAY INTERPRETATION

DR GEORGE W HOLMES I can state from the films in addition to what has already been said that the process is quite diffuse, involving both lungs, apparently most marked at the root and gradually spreading out into the periphery. There is very little normal lung visible. There may be some emphysema at the right apex. The heart shadow looks a little as though the auricles were dilated. The diaphragm is about normal in position. This appearance is consistent with a widespread bronchopneumonic process.

DR KING You would not call it tuberculosis?

DR HOLMES It could be a tuberculous bronchopneumonia. I do not think one can tell from x-rays alone what the etiologic factor is.

DR KING There are no definite cavities that you can see in these films?

DR HOLMES No.

DIFFERENTIAL DIAGNOSIS CONTINUED

DR KING So that we are again thrown back on a pneumonic process, it seems to me.

"On the eleventh day the sputum for the first time showed numerous acid fast bacilli." We cannot, therefore, doubt the presence of tubercle bacilli. We might want to. I think we have to assume that he has pulmonary tuberculosis unless by some chance there could have been a rupture of a gland into a bronchus as a terminal event and thus scatter a few "acid-fast red herring" across the trail. But I think we have to assume that it was pulmonary tuberculosis. The question is, is there a non-tuberculous pneumonia besides that? I think it is worthwhile going back over the story to see if the diagnosis of tuberculosis covers the whole picture. I do not see anything against tuberculosis in the history, although the explosive onset and the brownish sputum are more characteristic of pneumococcus infection than of an acute tuberculous process. Physical examination shows areas of consolidation throughout both lungs and these could be extensive tuberculosis. The herpes is perhaps more typical of pneumococcus infection. The "amphoric breathing" I will throw out since this is a very confusing sign. Certainly the x-ray does not show a cavity which would give amphoric breathing.

The laboratory findings are very important. I do not believe a white cell count running from 30,000 to 60,000 with 95 per cent polymorphonuclears is consistent with tuberculosis alone. I have never seen such a count in an uncomplicated tuberculosis. We have followed the blood of patients at the Channing Home for three years, running counts at least every month. The highest we have ever had is 20,000 and the polymorphonuclears do not usually run above 70 to 80 per cent. The present blood picture could be due to tuberculosis but I think it is distinctly unlikely. So that I would suggest that there is evidence here of infection other than tuberculosis and that it was a pneumonic process with tuberculosis as a complication. It is unusual for a tuberculous process to clear up on one side of the chest as this process did and spread later to the other side.

I should like to take a minute to show films on another case. The first x-ray was taken simply as a routine. Five months later the second film was taken, again as routine. The patient did not have a symptom or physical sign but the x-ray now shows a very small lesion with possible cavity. Three days later the x-ray was repeated and showed no change but again in three days there was a temperature of 101.4° and the patient had chills, malaise, and râles under the left clavicle. Four days after this there was positive sputum and definite x-ray evidence of an acute tuberculous pneumonia in the left

upper lobe I present this case to show that tuberculous can have an explosive onset and spread rapidly

In regard to the case under consideration for diagnosis I am going to make a diagnosis of non tuberculous pneumonia. The question then arises as to what organism may be responsible for the infection. The evidence as presented is in favor of a pneumococcus infection because pneumococci were found in the sputum and streptococcus was not shown in the throat culture. Nevertheless, the clinical course is much more like that of cases which we have been calling streptococcus pneumonia. We had quite a series of these cases a year ago. It is true, however, that we never fully established the streptococcus as the etiologic factor. In two cases of empyema following these infections however, streptococcus was recovered from the pus in the chest. So that on the basis of the clinical picture I shall make a diagnosis of streptococcus pneumonia and pulmonary tuberculosis.

DR. TRACY B. MALLORY: Have you any comment, Dr. Lord?

DR. FREDERICK T. LORD: The differential diagnosis between acute pneumoniae plithisis and pneumococcus lobar pneumonia is of special interest because of the benefits to be derived from specific serum therapy in certain types of pneumococcus infection. Diffuse infiltration involving an entire lobe is rarely observed with tuberculosis. It is usually endogenous in origin and occurs in consequence of the aspiration of the contents of a tuberculous cavity.

Regarding the symptoms, it is clear from the literature, especially the series of cases reported by Fraenkel and Troje, that there are significant differences in the clinical aspects of the two diseases. Patients with acute tuberculous lobar pneumonia are likely to have had previous manifestations suggesting the presence of a tuberculous process and at times hemoptysis is an initial symptom. The symptoms of onset are likely to differ from those with typical pneumococcus lobar pneumonia. The chill may be replaced by chilliness. Pain may be absent. The sputum is usually purulent and greenish rather than rusty. Tubercle bacilli are likely to be present. The temperature is more irregular and does not subside at the expected time. So far as the problem here is concerned, the symptoms of onset are atypical for acute pneumococcus infection and consistent with a tuberculous process. The marked leucocytosis is suggestive of a complicating non tuberculous infection.

The clearing of a part of the involved lung as shown by the x ray is more rapid than one would expect with tuberculous pneumonia but it should be appreciated that tuberculous lobar pneumonia is not necessarily caseous in the whole of the involved region. Surrounding

areas of caseation there is what Laennec spoke of as gelatinous infiltration. Microscopic examination shows alveoli filled with epithelioid cells and at the periphery the alveoli contain albuminous fluid and exfoliated epithelium. The process is partly due to an allergic reaction in an already sensitized individual and it has long been known that it is capable of partial resolution.

DR. ALFRED KRANES: We saw the patient on the ward and we too were very much puzzled as to whether he had tuberculous pneumonia or pneumococcus pneumonia. We thought later on that the presence of tubercle bacilli in the sputum was purely incidental and that the chief difficulty was the pneumococcus infection, that perhaps the acute pneumococcus infection had caused a focus of tuberculosis which was not very active to flare up and spread.

CLINICAL DIAGNOSES

Pulmonary tuberculosis
Lobar pneumonia

DR. DONALD S. KING'S DIAGNOSES

Streptococcus pneumonia
Pulmonary tuberculosis

ANATOMIC DIAGNOSES

Pulmonary tuberculosis, acute
Tuberculous pneumonia
Pleuritis, chronic fibrous.
Endocarditis acute terminal, mitral
Gastric ulcer

PATHOLOGIC DISCUSSION

DR. MALLORY: The difficulty in the differential diagnosis in this case was not so clearly understood and appreciated by us at the time of autopsy as I wish it had been. We found a very extensive pneumonic process irregularly scattered throughout all five lobes. At the left apex there were two definite cavities obviously tuberculous in character. Throughout the rest of the lung there were scattered tubercles in very large numbers, the majority of them isolated, but in some areas they were so close as to be confluent. Particularly in the lower lobes the tubercles became less obvious and one had a definite pneumonic process which I think could fairly be said to be a characteristic gelatinous pneumonia.

Microscopically the picture to my mind is consistent with pure tuberculosis. We have not attempted to stain streptococci or pneumococci in the sections, as perhaps we should do in order to rule out the possibility of superimposed infection, but we could find nothing in the sections that is not consistent with pure tuberculosis so far as cellular reaction is concerned.

DR. HOLMES: Was the cavity at the left apex very large?

DR MALLORY No, only two centimeters in diameter, the second one less than one centimeter

A PHYSICIAN Was there a polymorphonuclear exudate in the alveoli?

DR MALLORY The exudate is rather characteristic in that in the center of each alveolus or each group of alveoli there is a polymorphonuclear reaction and then at the periphery a mononuclear reaction. In some places there is beginning caseation, while in other areas the process has not gone far enough yet for caseation, though always the central mass is a leukocytic one. It is identical in appearance with experimental tuberculosis produced by massive doses of organisms. It is not a reaction that one sees very often in human cases. At the periph-

ery of the lesions there is much edema and epithelialization of the alveoli as Dr Lord suggested.

DR. KRANES It is rather interesting that the diagnosis of tuberculosis was first made by the house officer who admitted him because of an erroneous physical finding. The amphoric breathing which he found at the right apex made him think there was a large tuberculous cavity there, in addition to a pneumococcus lobar pneumonia. The rest of us could not confirm this finding so we dismissed the possibility of tuberculosis until the bacilli were found in the sputum. At autopsy there was nothing at the right apex, but there was a cavity at the left apex.

F E R A FOR PHYSICIANS

On page 130 is given an outline of a plan of the state F E R A authorities in cooperation with the Boston Department of Health, to furnish employment to indigent physicians. This plan will justify careful reading, not only by those who live in Boston, but by those residing elsewhere, inasmuch as it is the desire of the Federal government to cooperate with similar projects elsewhere if the need for them is shown.

As will be seen by studying Mr. Hobbs' letter these projects are designed purely for the relief of the actually destitute. It is very unlikely that anybody, no matter how poor he may think he is, or however deeply in debt, would be considered for employment if he or any member of his immediate family has a net income of \$10.00 to \$20.00 a week. The exact limit will depend on the number of his dependents. Before being acted on favorably all applicants will have to show at an interview with the Social Service

Department of the F E R A. that they are eligible.

Some confusion may be encountered at first in relation to the place of residence of the applicant. It is understood that the applicant must reside at the time of application in the City or Town in which the project is being carried on. This is mentioned because this rule differs from the rules in regard to soldiers' aid or ordinary public relief where the "settlement" is the determining factor in deciding which government unit is responsible to a given applicant.

Inasmuch as the *Journal* is read by only a part of the physicians in Boston, those in charge of this project would appreciate it if the names of those who might be eligible were called to their attention. Whether we approve or do not approve the general proposition of Federal relief, if there are instances of such poverty among physicians in Boston it is only fair to them to have this project called to their attention.

MORE SUPPORT FOR BIRTH CONTROL

In their meeting in Detroit on June 11, the General Federation of Women's Clubs by a vote of 493 to 17, recorded its approval of the dissemination of birth control information through scientifically regulated sources. This action was not taken hastily but was the outcome of a year of study by member clubs. The resolution asserted "it is of utmost importance to all Americans that the population of our country be vigorous and healthy both mentally and physically, and that proper and intelligent use of scientific contraceptive methods under direction of qualified and reputable physicians is essential to these ends."

This action supports the bills now before Congress which would exempt physicians hospitals and public clinics from the restrictions of the present Federal laws. Two of these bills, H. R. 5600 and S. 600, were introduced at the request of Mrs. Sanger, and a third bill, introduced by Senator Copeland and endorsed by the National Medical Committee on Birth Control Legislation, is intended to prevent the irresponsible distribution of contraceptive devices while at the same time it exempts physicians, hospitals and medical schools from the restrictions now in force.

The general opinion among those interested in the birth control movement is that the dissemination of contraceptive knowledge should be in the hands of the medical profession. In Europe the recognition of birth control as a public health measure is widespread. It is prohibited in those countries—Germany, Italy and France—which are engaged in competition for military supremacy. The Ministry of Health in Great Britain has officially recognized birth control as a public health measure. That public sentiment

ment in this country is tending more and more to favor a properly regulated dissemination of contraceptive knowledge is clearly indicated by its endorsement by many churches, religious societies, welfare groups and professional organizations, and by the recent action of the New York Medical Society and the House of Delegates of the American Medical Association

,House 2245 which relates to "an investigation and study by the Commissioner of Public Health of the laws relative to public health and to the establishment and administration of a system of health insurance," which was referred to the next annual session of the House, July 9, 1935, was refused reconsideration July 11, 1935

MISCELLANY

F E R A FOR PHYSICIANS IN BOSTON

A project for the employment of physicians in the City of Boston by the E R A is in the process of formation On July 7, 1935, the following letter was sent to the Boston members of the Suffolk District Society

"To Boston Members of the Suffolk District Medical Society

"The Society has been advised by representatives of the Federal Government that medical employment will be found whenever possible for those physicians who are residents of Boston and who are in urgent need of financial relief The type of employment will be limited in the main to preventive medicine and in no way offers reimbursement for private practice

"If you know of any physician who falls in the above class, kindly send in the name and address at once to the secretary

"Very sincerely yours,

"ROBERT L DE NORMANDIE, *President*"

Since then similar letters have been sent to Boston members of Middlesex South and Norfolk Societies It is the purpose of the project to employ all doctors, not necessarily members of the Societies, who meet the following qualifications They must be legal practitioners in medicine They must be residents of Boston They must be in such financial need that they are eligible for E R A aid, and they must be employable

The present project will be under the direction of Dr Wilinsky of the Boston City Department of Health and will consist of work in the various health units He will have nothing to do with the choosing of the men to work Applications should not be made to him. Applicants will be examined by the Social Service Department of the E R A., at the Boston Medical Library, by appointment Applications should be made first to the secretary of the proper District Society Dr A. A. Levi, 485 Commonwealth Avenue, for residents of Allston, Brighton and Charlestown Dr Frank S Crulckshank, 1236 Beacon Street, Brookline, for residents of Roxbury, Dorchester, Hyde Park, Roslindale and West Roxbury, and Dr Charles C Lund, 319 Longwood Avenue, Boston, for the rest of Boston

The following letter from Mr Hobbs explains the general background of this type of project and may

be of interest to those who are thinking of initiating such projects elsewhere in Massachusetts

"The first thing that we wish to impress upon you in regard to the Emergency Relief Administration is the fact that all projects should be built up around the needs of the community. Fine as a project may be in itself the E.R.A. is not officially interested unless it provides suitable work to a needy person

If there is a group of doctors in the community who are in as great need as any others then we wish to develop projects for them

Once the need has been established then the problem is to employ this group in the most profitable way possible. The project must be of economic and social value and must be for the benefit of the community at large. The E.R.A. cannot perform services for private institutions or for individuals

Many months ago we determined that doctors and dentists should be paid \$20.00 a week for thirteen hours service. A few simple rules were prepared for dentists copy of which we enclose and which would apply with equal force to doctors

We wish to warn you that the rules which we have stated above will be modified when the E.R.A. is transferred into the W.P.A. and this will probably come within a few weeks. Under the W.P.A. technical and professional employees will be paid \$24.00 a month in Suffolk and Middlesex Counties, \$33.00 a month in Norfolk. Other counties I do not believe you are interested in at the present time

Projects in Suffolk County will be under the direction of Col. Thomas F. Sullivan 1 Beacon Street, Boston and projects in Middlesex and Norfolk Counties will be under the direction of Mr. Byrle Osborne 49 Federal Street, Boston

"This is a very brief outline of the situation and if there is any further information which you would like please let me hear from you.

Sincerely yours

"CONRAD HOBBS

By direction of Howard P. Philbrook
Director of Work Division Federal
Emergency Relief Administration
of Massachusetts

49 Federal Street,
Boston Mass

THE APPOINTMENT OF DR. FREDERICK F RUSSELL

Dr. Frederick F. Russell of the Rockefeller Foundation will retire September 1, 1935 to fill an appointment as Lecturer on Preventive Medicine and Hygiene and Epidemiology at the Harvard Medical School.

He was graduated from the College of Physicians and Surgeons, Columbia University with the additional title of Sc.D. from George Washington University

On December 12, 1898 he became Commandant 1st Lt. Asst. Surgeon U.S.A. Colonel in 1917 and re-

signed in 1920. Since 1921 he has held several positions in Washington and was in charge of the Division of Infectious Diseases and of the Laboratory Service of the Surgeon General's Office U.S.A., during the World War

Dr. Russell is a Fellow of the American College of Surgeons, American Public Health Association, the New York Academy of Medicine and a member of the American Medical Association and the Royal Medical Society of Budapest, Hungary

RECENT DEATHS

DOWLING—JOHN JOSEPH DOWLING M.D., Superintendent of the Boston City Hospital died at his home on the hospital grounds July 10, 1935 of cerebral thrombosis following an attack of pneumonia superimposed on a long illness

Dr. Dowling had recently been granted a leave of absence with the hope of recuperating from an extended period of impaired health

He was appointed Superintendent of the Hospital by Governor Curley upon his Excellency was Mayor of Boston. Dr. Dowling is credited with the enlargement and modernization of the hospital while serving under a succession of Governors since his first appointment.

Dr. Dowling was born in Boston in 1870 and attended the public schools and the Boston Latin School. He graduated from the Harvard Medical School in 1894 and pursued postgraduate studies in Dublin and London. On returning to Boston he developed a large practice in Roxbury, Dorchester and the South End relinquishing this to become the superintendent of the largest municipal hospital in the country

He served in the World War as head of the Boston City Hospital Base Hospital No. 7 unit and returned to Boston with the rank of Lieutenant Colonel

Dr. Dowling was a Fellow of the Massachusetts Medical Society and the American Medical Association, the Harvard, the Clover and the Boston City Clubs

He is survived by his widow Mrs. Marcela Pugh Dowling, a daughter Miss Barbara Dowling, a son, Mark Dowling and two brothers Mark Dowling and Frank Dowling both of Boston.

MURPHY—JOHN JOSEPH MURPHY M.D., of 2192 Massachusetts Avenue North Cambridge, died suddenly July 8 at North Conway, New Hampshire while on a vacation with Mrs. Murphy

Dr. Murphy was born in 1886 and his early education was acquired in the Cambridge High and Latin Schools and Holy Cross College. He received his M.D. degree from the Harvard Medical School in 1913 and served an internship at the Boston City Hospital and the Boston Dispensary

He enlisted in the army in 1916 as a Lieutenant in the medical corps and was advanced to rank of captain in 1917 and served at Camp Benjamin Harri-

without also reacting to foods These were all older children

II AND III

Twenty-five cases were tested with patch tests according to the usual patch test technique, using Arlington proteins*

In this series the proteins used were

Cat hair	Silk
Dog hair	Wool
Chicken feather	Cottonseed
Goose feather	

There were no positive reactions whatsoever

Most of Dr Peck's positive patch tests were to feathers In a series of twenty-five consecutive cases in Boston, it was found that only five slept on feather pillows Dr Peck told me that almost all of the babies coming to his Clinic slept on feather pillows This may partly account for the difference in our results, and it must be remembered that in different localities different sensitizations occur, according to what allergens the susceptible individuals are most frequently exposed Thus in New York, scratch reactions to rabbit hair are very commonly obtained, in our series of sixty tested with rabbit hair, there was only one positive reaction

Next, a series of twenty cases who gave a positive scratch test to some environmental allergen, were tested by the patch method with the same allergen, sometimes using the powdered

TABLE 4

21 Timothy		0
22 Silk		0

reacted by the sera'oh test, was applied, plus diluent, to the untranmatized skin (shown in table 5)

It was found, however, that if the epidermis was very slightly abraded with the blunt end of a throat stick, a positive reaction could always be obtained, provided the scratch test was positive. This was tried in seven cases (Shown in Plate 1)

Cases 1 and 17 are of partienlar interest. Case 1 was two years old with a moderate amount of eczema, and a very largo scratch test to egg white. She was playing in the kitchen one day with some egg shells, and hives immediately appeared on her hands and arms. She reacted with a large wheal when egg white powder plus saline was applied to the unbroken skin. Case 17 was

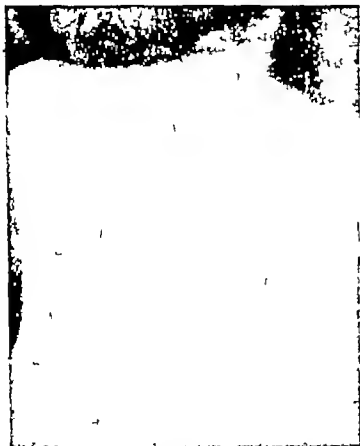

PLATE 2

Left wheat protein powder plus diluent laid on unbroken skin.
Right scratch test with wheat protein powder

eight months old, with a very severe eczema. Strongly positive scratch tests to wheat and lactalbumin. On a wheat and milk free diet his eczema was nearly cured. One day when he was about a year old his mother gave him a flour-sifter to play with which had considerable flour on it. He got a good deal of flour over his face and hands and the next day appeared in the Clinic with acute dermatitis of the face and upper part of the body. A large immediate wheal reaction was obtained by applying wheat protein powder plus diluent, to the unbroken skin. (Shown in plate 2)

Such cases as these two are the exception rather than the rule.

In 1887, Dr James C White then professor of dermatology in the Harvard Medical School wrote a monograph which has become a classic

of dermatologic literature, entitled "Dermatitis Venenata, An Account of the Action of External Irritants Upon the Skin." In it he showed that in addition to poison ivy, there were many other plants and chemical substances which could cause intense dermatitis, and brought out particularly the fact that many of these substances were harmless to the ordinary person, and that their deleterious action was dependent upon a special idiosyncrasy of the individual.

In the succeeding years the importance and frequency of these eruptions began to be more generally recognized, particularly in industrial workers, who were exposed to all sorts of substances during the course of their work. It was not, however, until the younger Jadassohn and Bloch, less than ten years ago demonstrated that these eruptions were of an allergic nature and more extensively employed the patch test, which had first been used by the older Jadassohn in 1895, that their true significance was understood.

They believed that in most cases of eczema in adults the sensitization is of the epidermal type, that the dermatitis is due to external contact with innumerable substances usually of non-protein nature and their school confines the terms "eczema" to this type of eruption, which is the same as the older "dermatitis venenata." Their teachings were introduced into America by their pupils (Sulzberger, Peck and others) a very few years ago and have been of great value in explaining many obscure eruptions.

Sulzberger and Coca have pointed out, however in several publications, that there are two sorts of skin sensitization, one the "eczema" of Bloch and Jadassohn where the sensitization is epidermal to some non-protein substance, tested for by means of the patch test, with no reactions demonstrable in the blood, no history of hereditary transmission, and no association with asthma and hay fever. The other type of skin sensitization is not of the epidermis but of the deeper layers of the skin and is tested for by means of the scratch or intracutaneous test. The sensitization here is to proteins or protein-like substances, is often hereditary, and often associated with asthma and hay fever.

For this symptom complex, which in some cases may have almost the aspect of a distinct disease entity, Coca suggested the word "atopy", and most American dermatologists call the first type of sensitization "contact dermatitis." Coca and Sulzberger have repeatedly insisted that the two conditions, although both coming under the head of allergy are different in their mechanism and that the patch test is suitable for contact dermatitis but not for atopy. Peck has said, however, that there is no essential difference between the two and that the eczema of infants differs in no way from the 'contact dermatitis' of adults.

There seems to be no question whatever that there are these two types of allergic skin sensitization which have, possibly, certain similarities in their basic nature, but are dissimilar enough in actual practice to warrant separate classification. Most dermatologists have accepted these conceptions.

The question is how much do they overlap? Do protein atopens commonly cause skin symptoms by simple contact with the epidermis? Do infants and young children have the non-atopic contact dermatitis, with sensitization to non-protein allergens, and if so, how common is it?

From our own work it seems that protein allergens *can* act on the intact epidermis (cases 1, 16, 17), but that this is unusual, and that the element of rubbing, or some slight trauma to the outer layer of the skin, is usually necessary before the allergen can come into contact with the sensitized cells, which lie below the epidermis. For this reason the patch test is quite unsuitable for use in most infants and children with eczema, who usually have the atopic type of sensitization. The situation is different with adults in whom the epidermal type of sensitization to non-protein allergens is more common.

Piness, Sulzberger and Vaughan, and Figley and Parkhurst, have also clearly pointed out that environmental atopens such as silk, horse dander and pollens, when inhaled, can easily reach the sensitized cuticular cells through the blood stream, and cause skin symptoms in this way. It seems likely that they most often work in this way, but some allergens, particularly silk, wool, and cat hair (in fur collars) may often cause symptoms by contact. The contact, however, is usually not *simple* contact, and the element of rubbing may be necessary.

In order to avoid confusion, it is well, however, not to call any eruption caused by protein allergens "contact dermatitis", but rather "atopic dermatitis" or "atopic eczema".

The question of true contact dermatitis to non-protein allergens in infants and young children, is practically an unexplored field. It is certain that it can occur (primrose, poison ivy), and we have seen recently one case due to turpentine sensitization, and one to the dye in a dark blue "snow suit", both in young children.

The infant and young child, however, come into contact with relatively few of the substances which cause this type of eruption in the adult, and when contact dermatitis does occur in infants and young children there is likely to be an obvious cause and effect relationship between some definite irritant and the eruption. With the adult, who may be exposed to so many possible irritants, this is not so likely to be the case.

It seemed worth while to do routine patch

tests with some of the more common possibly eczematogenous substances to which infants and young children might be exposed, in order to determine the frequency of this type of sensitization.

A series of twenty cases were tested by means of the patch tests with the following substances

*Soap 1	Mercuric chloride
Soap 2	Olive oil
Soap 3	Cottonseed oil
Soap 4	Rose geranium oil
Soap 5	
Paraphenylenediamine	

Paraphenylenediamine or "ursol" is a derivative of aniline, and is the base of certain dyes, particularly those used for dyeing fur. This and mercuric chloride were used because they give so many positive reactions in adults. Rose geranium oil is used as a scent for many soaps and powders. In adults sensitization to such essential oil is common.

In this series of twenty patients there were fourteen under one year of age and six over one year. One patient, aged three months, gave delayed reactions to olive oil, mercuric chloride and paraphenylenediamine. It could not be shown, however, that any of these had anything to do with the eczema. In the other nineteen patients there were no positive tests whatever.

The few cases of contact dermatitis that we have seen have been acute, occurring suddenly on previously healthy skin, usually on the exposed surfaces, such as the back of the neck, the face, or the legs, and have been vesicular in character, similar in every way to a poison ivy eruption. If such eruptions occur it is worth while to do patch tests with any suspected substances to which the child has been exposed, but in most cases of eczema in the young, patch tests are not desirable or necessary as a routine measure.

IV

It is clear that positive scratch tests to environmental protein allergens are occasionally obtained in eczematous infants, and often in older children. These allergens should therefore be used as a routine in testing, just as they are in asthma, and must be taken into account in any consideration of etiology and treatment, but it is not always possible to prove that they are causing the eczema, for there is almost always sensitization to foods as well. The situation is by no means so clear as it is in hay fever, where there is likely to be sensitization to one very definite pollen group, and a definite cause and effect relationship between symptoms and exposure. To illustrate this the following case reports, some very doubtful, some clean cut, are of interest, and show some of the

*These are all common soaps used either to wash the baby or the clothes and linen with which he comes into contact. It is thought best not to give their trade names.

difficulties involved, if one is critical, in arriving at accurate conclusions

CASE 1 Aged six months His father and four months have hay fever He has had facial eczema for two months For the last two weeks the mother had noticed that about noontime each day shortly after eating his face became much redder than usual and small hives appeared on his neck, arms and legs These would last about half an hour and then disappear It was thought by the mother that various articles of food which he ate for his dinner were responsible for the hives and some of these were omitted but the hives persisted A complete set of skin tests was done, with positive reactions only to egg and silk (he had never eaten eggs) It was found on questioning that after his dinner his mother always held him and that at this time she always wore a silk wrapper against which he rubbed his arms and face

The silk wrapper was omitted and he had no more hives The facial eczema did not improve however in spite of great care in removing silk from the environment. It is certain that the hives were caused by silk It cannot be concluded however that the facial eczema was

CASE 2 A child twenty-seven months old with a severe chronic eczema of the disseminated neurodermatitis type

His tests were positive to egg white peas and horse dander He ate peas occasionally and although he did not eat eggs it is probable that he ate egg-containing food

When asked if the child ever came into contact with horses, the mother said "He has never even seen a horse," but on closer questioning it was found that his older sister rode horseback and that the patient was in the habit of spending a good deal of time in her closet where she kept her riding clothes playing with her riding boots

Egg-containing food and peas were omitted from his diet and he was kept out of the closet His eczema was considerably improved to a month but by no means cured.

This case is suggestive but not entirely conclusive

CASE 3 A boy two and a half years old whose mother had hay fever had had eczema since the age of two months He gave strongly positive scratch tests to dog hair silk codfish lactalbumin wheat, and oats As far as could be ascertained he did not come into contact with dog hair or silk

The foods to which he was sensitive were omitted from his diet, with very good results and in about two months his eczema was cured This case proves nothing for although he had marked reactions to silk and dog hair he was apparently not exposed to them (although he might have been inhaling silk) and he was sensitive to two very important foods (wheat and milk)

CASE 4 A boy four and a half years old had had eczema ever since the age of six months At the time of examination he had a moderate amount of chronic eczema back of the knees There was a positive reaction to horse dander and to nothing else On questioning the mother said that one horse was occasionally pastured in a field near their house and that the boy had on several occasions patted the horse but came into contact with horses or with anything pertaining to horses in no other way He was told to keep away from the horse, and was given two x-ray exposures to the areas of eczema on his legs Although there was no food sensitization in this case, and there was definite horse dander sensitization, the conclusion is not warranted that the

horse dander sensitization was the cause of his skin symptoms, on account of the infrequent and slight exposure and it is very likely that the x-ray treatments cured his eczema

CASE 5 A boy twenty-two months old had had a severe eczema since the age of six months Skin tests were positive to elk cottonseed kapok egg white egg yolk asparagus potato and beef The foods to which he was sensitive were omitted from his diet and he was given a hair mattress instead of the kapok one which he had had before Also local x-ray treatment Very satisfactory results In this case there was very definite continuous exposure to kapok and although there was sensitization to foods and other environmental allergens as well it seemed that kapok sensitization had a good deal to do with his eczema, as he was continually exposed to it

CASE 6 A boy twelve years old whose father was asthmatic had had eczema continually since he was eighteen months old It was so bad that the parents had about given up hope of its ever improving The boy himself knew that he was exquisitely sensitive to cats for several times after exposure he had had mild attacks of asthma and flare-ups of his eczema As far as he knew he was sensitive to nothing else

Skin tests had marked reactions to cat hair and rabbit hair all others were negative He had been having rabbit hair exposure from a coat of his sister's He was kept away from cats and the rabbit fur coat was laid away His eczema was almost entirely cured in about six weeks Although this boy was also given local treatment it seemed reasonably certain that sensitization to rabbit hair and cat hair was very definitely the cause of his eczema

SUMMARY

Scratch tests to environmental allergens were positive in ten per cent of thirty-eight eczematous infants under one year of age, in thirty seven per cent of fourteen infants between one and two years of age, and in fifty per cent of forty-nine children between two and twelve years of age

In a series of twenty-five cases tested by means of the patch test with protein environmental allergens, there were no positive reactions

Twenty-one cases which gave positive scratch tests to an environmental allergen were tested by means of the patch test, with the same allergen There was only one positive test This was manifested by whealing and not by the usual vesiculation and scaling ordinarily seen in positive patch tests with non-protein substances.

In twenty-two cases which gave positive scratch tests, application of the reacting protein to the unbroken skin caused an immediate wheal reaction in only three cases but when the skin was gently abraded with the end of a throat stick before applying the protein a reaction invariably followed. (Seven cases tested)

Twenty cases were tested with ten common environmental non-protein substances by means of the patch test. There were positive reactions in only one patient.

CONCLUSIONS

1 The animal epidermals and other so-called environmental allergens should be taken into consideration, as well as foods, in any attempt to discover the etiology of eczema in infants and children. Their importance is not great during the first year of life. After the second year they are equally as important as foods.

2 The patch test is not the correct test to use in testing with protein allergens.

3 Protein allergens can act on the untrau-

matized epidermis, but this is unusual. Certain of them probably often act by contact if there is prolonged rubbing or slight trauma. They also act by inhalation.

4 Contact dermatitis caused by non-protein allergens is not common in infants and young children.

RÉSUMÉ OF COMMUNICABLE DISEASES
IN MASSACHUSETTS FOR JUNE, 1935

Disease	June, 1935	June, 1934	5 Yr Average*
Anterior Poliomyelitis.....	6	5	6
Chicken Pox	1051	1149	1017
Diphtheria	36	41	113
Dog Bite	1327	1262	868
Epidemic Cerebrospinal Meningitis	2	5	8
German Measles.....	5898	92	282
Gonorrhea	526	566	600
Lobar Pneumonia.....	272	241	218
Measles	1486	3380	3252
Mumps	406	467	607
Scarlet Fever.....	742	731	930
Syphilis	418	426	388
Tuberculosis Pulmonary.....	331	333	360
Tuberculosis Other Forms.....	30	41	46
Typhoid Fever	6	4	13
Undulant Fever	3	2	
Whooping Cough	361	970	729

*Based on the figures for the preceding 5 years

RARE DISEASES

Anterior poliomyelitis was reported from Boston, 1, Chicopee 1, Everett, 1, Lawrence, 1, Manchester, 1, Swampscott, 1, total, 6

Dysentery (bacillary) was reported from Malden, 1

Malaria was reported from Belmont, 1, Springfield, 1, total, 2

Cerebrospinal meningitis was reported from Lynn, 1, Malden, 1, total, 2

Paratyphoid fever (B) was reported from Boston, 1

Pellagra was reported from Cambridge, 1

Septic sore throat was reported from Auburn, 1, Boston, 3, Bridgewater, 1, Cambridge, 1, Fall River, 1, Lexington, 2, Lynn, 1, Medford, 1, Montague, 1, Northbridge, 1, Springfield, 1, Topsfield, 2, Waltham, 1, total, 17

Tetanus was reported from New Bedford, 1

Trachoma was reported from Chelsea, 1, Lawrence, 1, total, 2

Trichinosis was reported from Brookline, 1

Undulant fever was reported from Brookline, 1, Danvers, 1, Wellesley, 1, total, 3

Diphtheria shows a decrease of 33 per cent for the

first six months of the year as compared with the same interval in 1934

Infantile paralysis and epidemic cerebrospinal meningitis are being reported in normal figures to date

German measles, although still epidemic, had its peak in May

Reported tuberculosis morbidity remained well below the five year average

Lobar pneumonia and typhoid fever are running slightly higher than in 1934, while scarlet fever, mumps, whooping cough and measles are being reported in lower figures than the preceding year

Chicken pox and tuberculosis other forms show nothing remarkable

HAY FEVER AND COLDS

That people who suffer from hay fever in summer are more susceptible than others to common colds in winter, but if treated with pollen extract for hay fever they show greater immunity to colds later, was stated in New York, on July 15, as a result of observations made over a period of six years at Beth Israel Hospital

In a report published in the July 15 issue of the *New York State Journal of Medicine*, Dr. Louis Sternberg, who made the study among patients at the hospital, says "The author has reviewed the histories of 200 treated cases of hay fever observed from 1 to 6 years, and finds that 53 gave a previous history of frequent colds usually in winter. After their first seasonal or perennial course of treatment with pollen extract, 36 of the 53 stated that they had been relieved of head colds throughout the winter months following their treatments. Of this total number, 25 were sensitive to ragweed, 8 to timothy, and 3 to both ragweed and timothy. The 17 cases not relieved of winter colds did not have much relief from the pollen injections.

"The reason," states Dr. Sternberg, "for this apparent immunity to the infection known as the common cold is not now known. It is presented as a clinical fact that remains to be explained. That those suffering from hay fever or asthma are generally more subject to upper respiratory infections than other individuals is a well-known fact, but few among the numerous publications on the 'common cold' have ever mentioned how these colds are influenced by pollen treatment in hay fever subjects."

The Massachusetts Medical Society

PROCEEDINGS OF THE COUNCIL

Annual Meeting, June 1, 1935

THE annual meeting of the Council was held in the Georgian Room of the Hotel Statler Boston, Mass., on Tuesday, June 4, 1935, at 12 o'clock, noon. The President, Dr. William H. Robey, Suffolk, was in the chair and the following 227 Councilors were present:

After calling the Council to order President Robey announced that Councilors only were supposed to be at the meeting and stated that if there were any representatives of the press in the room, he would ask them to retire and that any information which was to be released could be obtained when the meeting was over. He then called upon the Acting Secretary who read in abstract the report of the last meeting. There being no errors or corrections the President declared it approved.

President Robey next read the obituaries of two Councilors who have died during the year.

DR. GEORGE HOYT BIGELOW of Milton, Massachusetts, died December 3, 1934. He was born in 1890 the son of Dr. E. H. Bigelow and Mrs. Agnes Elizabeth (Cutter) Bigelow, graduated from Harvard College in 1912 and from the Harvard Medical School in 1916. After an internship at the Massachusetts General Hospital, he joined the medical corps of the United States Army, serving at the Rockefeller Institute, Fort Sam Houston, base hospital at Spartanburg and overseas at Allercy. On returning to this country in 1919, he engaged in the study of frambesia in Santo Domingo, later returning to the Harvard School of Public Health, graduating therefrom in 1921. He accepted a position in Antioch College in the department of industrial medicine and later Cornell Medical College as director of the clinic.

In 1924 Dr. Bigelow became Director of the Division of Communicable Diseases in the Massachusetts Department of Public Health rising to the position of Commissioner of Public Health in less than two years. In 1933 he resigned and was appointed Director of the Massachusetts General Hospital to occupy the position made vacant by the resignation of Dr. F. A. Washburn.

His administration of the Department of Public Health was marked by notable contributions to sanitation and extension of service in many other ways. The Massachusetts cancer program with the hospital at Pondville will stand as one of the important contributions to progress in this Commonwealth which led to his election as President of the American Society for the Control of Cancer.

Dr. Bigelow was a Fellow of the Massachusetts Medical Society, the American Medical Association, and a member of many national and local societies.

He is survived by his widow Mrs. Margaret (Wesselhoeft) Bigelow, two children, a daughter of sixteen and a son of fourteen years, his father and mother, Dr. and Mrs. Enos H. Bigelow of Framingham, and two brothers.

DR. HARRY WINFRED GOODALL of Boston, Massachusetts, died April 17, 1935, after an illness of several months. He was born at Wells, Maine, in 1876, the son of George B. and Isabel M. (Norton) Goodall.

His premedical education was acquired at Berwick (Maine) Academy and at Dartmouth College, taking his A.B. degree in 1898 with honors. He graduated from the Harvard Medical School, summa cum laude, in 1902, and served an internship at the Massachusetts General Hospital, and later at the Boston Lying In Hospital. He was also assistant resident physician at the Massachusetts General Hospital. He studied at the University of Tübingen, Germany, in 1908. He lectured on digestive diseases at the Dartmouth Medical School and was instructor in Chemistry at the Harvard Medical School for a time.

His hospital associations were with the Boston Dispensary, New England Baptist, Peter Bent Brigham, Phillips House, New England Deaconess, Palm

er Memorial, Chelsea Memorial, Burbank Hospital, Fitchburg, Symmes Hospital, Arlington, Sturdy Hospital, Attleboro, Framingham Hospital, and Home for Aged Couples, Roxbury, in several of which he acted as chief.

Dr. Goodall began his military service as major in the Army Medical Corps in 1917. After serving at Camp Greene, N. C., and Camp Wheeler, Ga., he went overseas in August 1918. He was commissioned Lieutenant Colonel, August 9, 1918. He served as commanding officer of the gas hospital at Toul, France, and chief of the medical service at a base hospital until the close of the war. He was cited for meritorious and distinguished service.

He was the author of several important contributions to medical publications.

Dr. Goodall joined the Massachusetts Medical Society in 1904 and was a member of the Council. His other Society memberships include the American Medical Association and the American College of Physicians.

The Council rose for a period of silence in respect to the memory of these men.

The Acting Secretary then called the roll of the Nominating Councilors and the following responded to their names and retired to prepare a list of nominations.

W. D. Kinney, *Barnstable*, H. J. Downey, *Berkshire*, W. H. Allen, *Bristol North*, E. F. Cody, *Bristol South*, J. F. Burnham, *Essex North*, C. L. Hoitt, *Essex South*, H. M. Kemp, *Franklin*, G. L. Schadt, *Hampden*, J. G. Hanson, *Hampshire*, R. R. Stratton, *Middlesex East*, F. R. Mahony, *Middlesex North*, A. W. Dudley, *Middlesex South*, W. A. Griffin, *Norfolk*, C. A. Sullivan, *Norfolk South*, T. H. McCarthy, *Plymouth*, Lincoln Davis, *Suffolk*, David Harrower, *Worcester* and H. R. Nye, *Worcester North*.

The business of the meeting then proceeded with the presentation of the report of the Committee on Membership and Finance by the Chairman, Dr. D. N. Blakely of Norfolk. This report was accepted and its recommendations adopted. (See Appendix No. 1.)

The Acting Secretary next presented the following petitions for restoration to membership. Each was recommended by the committee chosen and, under the usual conditions, was accepted by vote.

(1) Abraham Burack, Brockton (Committee J. J. McNamara, A. C. Smith and Thomas H. McCarthy)

(2) Alfred W. Butler, Watertown (Committee H. Q. Gallupe, Dwight O'Hara and H. F. Day)

(3) C. A. C. Richardson, Somerville (Committee F. L. Morse, C. L. McCrossan and E. F. Sewall)

The President then nominated and the Council appointed the following committees to consider the designated petitions for restoration to membership.

For Charles McGinley, Lynn

C. L. Hoitt, W. L. Fraser and O. C. Blair

For Mario J. Cariani, Springfield
J. M. Birnie, M. F. Hosmer and T. S. Bacon

For Henry Ritter, Springfield
G. L. Steele, E. E. W. Walker and M. J. Stoddard

The President then called upon the Treasurer for a report and Dr. C. S. Butler of Suffolk stated that, while it was his impression that the Treasurer's report should be given at the Annual Meeting of the Society and therefore did not have the written report with him, he thought he could give an outline of what it contained. The report was accepted. (See Appendix No. 2.)

The President then called for a report of the Committee on Ethics and Discipline which was read by the Chairman, Dr. David Cheever of Suffolk. The report was accepted. (See Appendix No. 3.)

Dr. Roger I. Lee of Suffolk, Chairman of the Committee on Publications, stated that there was no formal report. He thought that the *Journal* spoke for itself. He stated that the only activities of the Committee on Publications were the moral supervision of the *Journal* and the election of the Shattuck Lecturer. He said, "We had the Shattuck Lecture last night and we get the *Journal* every week."

The report of the Committee on Medical Education and Medical Diplomas was presented by Dr. Reginald Fitz of Suffolk. The report was accepted. (See Appendix No. 4.)

The report of the Committee on State and National Legislation was presented by the Acting Secretary. This report was accepted. (See Appendix No. 5.)

Dr. Dwight O'Hara of Middlesex South then presented the report of the Committee on Public Health which was duly accepted. (See Appendix No. 6.)

Dr. Franklin G. Balch of Norfolk then presented the report of the Committee on Malpractice Defense which was duly accepted. (See Appendix No. 7.)

Dr. Robert B. Greenough of Suffolk stated that the Committee on Permanent Home had no new matter to add to the report which it gave at the meeting of the Council in February and suggested that with the Council's approval he would submit this report, as written to the Secretary. (See Appendix No. 8.)

In the absence of Dr. George R. Minot, Dr. Walter Baner of Suffolk was given the privilege of the floor to present the report of the Committee Appointed to Consider the Situation Regarding Rheumatism and Allied Diseases in Massachusetts. (See Appendix No. 9.)

Considerable discussion followed the reading of this report. Dr. Francis P. McCarthy of Norfolk felt that the Society should go slowly in placing one more medical matter under state control. He stated that he believed more study

was needed and he therefore moved that the matter be laid on the table.

Dr. George C. Shattuck of Suffolk stated that because of the large number of cases of chronic rheumatism in the state the matter was so serious and the solution offered of such obvious value that he believed the state should undertake to handle the problem.

Dr. George P. Reynolds of Suffolk agreed with Dr. Shattuck and brought in before the meeting a large chart which showed that rheumatism is the greatest cause of chronic disease in Massachusetts. He referred to the number of individuals involved and gave some statistics from the European experience.

Dr. James H. Means of Suffolk felt that the matter should be settled and should be discussed from the point of view of what is best for arthritis. He did not feel disturbed over Dr. McCarthy's suggestions that this will mean more state medicine. He referred to the cancer situation and the work done at Pondville. He stated that he believed the cancer situation in the state is better than ever before.

Dr. Shields Warren of Suffolk spoke as a pathologist rather than a practitioner of medicine. He reminded the Council that there is no disease "rheumatism" as such, but that rheumatism is made up of a vast number of symptoms which arise from a variety of pathological processes and that in approaching the problem of rheumatism the entire problem of degenerative diseases must be given consideration. He felt that it was unwise to establish a large hospital on so nebulous a basis and suggested that we make better use of those agencies already existing. He referred to the work being done at the Massachusetts General Hospital and the Robert Brigham Hospital. He stated that he would like to see the Society place itself on record as favoring an investigation of the problem of rheumatism and of working out some satisfactory means of handling it rather than to place itself on record as favoring the addition of two hundred and fifty beds to an already over-institutionalized state.

Dr. E. P. Joslin of Suffolk stated that he had been in conversation with Dr. McCarthy who was apparently agreeable to the acceptance of the proposed plan provided the word "public" was omitted. He stated that in his own case at the present time he would rather see the work proceed under private auspices.

Dr. McCarthy of Norfolk stated that he believed that we already have adequate facilities in the state to take care of the rheumatism problem and reaffirmed his motion to lay the matter on the table.

Dr. H. M. Landesman of Norfolk felt that it would be a bad precedent to ask for the establishment of such a hospital. He likewise re-

ferred to the existing facilities which were not being used to the fullest extent

The President then put the question and, after calling for a rising vote, decided that the motion was carried and that the report of the Committee would therefore be placed upon the table

The Nominating Committee next presented its list of candidates for the ensuing year which was as follows

For President Charles E Mongan, Somerville
For Vice President Channing Frothingham, Boston
For Secretary Alexander S Begg, West Roxbury
For Treasurer Charles S Butler, Boston.
For Orator Reginald Fitz, Boston.

Upon motion of Dr W A Lane of Norfolk, it was unanimously voted to instruct the Secretary to cast one ballot for the candidates named above Under the instruction of the above motion the Acting Secretary cast the ballot as directed President Robey therefore declared the gentlemen duly elected At his request Dr Mongan came forward to sit upon the platform

The meeting then adjourned at 1 15 P M for luncheon

The President called the meeting to order at 2 00 P M There being no report from the Committee on Physical Therapy, Dr Balch presented the report of the Committee on Cancer which was accepted (See Appendix No 10)

Dr Dwight O'Hara of Middlesex South stated that there was no special report from the Committee on Public Education as it is included in the report of the Committee on Public Health

The Acting Secretary presented the report of the Committee on Postgraduate Instruction which was accepted (See Appendix No 11)

The President announced that the work of the Public Relations Committee had been divided among five subcommittees and then proceeded to call upon the Chairmen of the several Subcommittees for a report of their activities

Dr Ernest L Hunt of Worcester presented the report of the Subcommittee on the Adequacy of Medical Care which was accepted (See Appendix No 12)

Dr Channing Frothingham of Suffolk presented the report of the Subcommittee on Public Health and Practitioner and Public Information The report was accepted. (See Appendix No 13) Dr Frothingham then moved that the Council adopt the recommendations contained in the report There was some discussion regarding the wording of the recommendation concerning Public Information and it was finally voted to alter the original phraseology to read as now printed in the report

Dr F H Allen of Hampden asked to be informed concerning the recommendation regarding the care of the indigent sick He desired

to know if local physicians are to give free care to patients recommended to them by local boards of health or referred to them by local health organizations, or does it have some reference to the plan adopted in Franklin County where by all indigent sick are treated at a reduced fee rate by any physician they wish to call

Dr Frothingham believed it to be the idea of the committee that it would be desirable to have the indigent sick cared for by individual physicians rather than by salaried city physicians or whatever title such persons should be given, and that the welfare department should work out a plan with the doctors so that the fees would go to the individual physicians rather than to some one on salary The recommendations were then approved as altered

Dr Tighe of Middlesex North submitted the report of the Subcommittee on Social Legislation and Insurance which was duly accepted (See Appendix No 14)

Dr Blaisdell of Middlesex East then presented the report of the Subcommittee on Hospital Relations (See Appendix No 15) This was duly accepted

Dr Dunbar of Bristol North stated that the Subcommittee on Medical Education and Licensure had no report to render at this time

At the request of President Robey, Dr Walter P Bowers of Worcester stated that the New England Medical Council had suspended operations since the Medical Society of Rhode Island was no longer able and willing to contribute its proportionate share of the expenses of the Council This report was accepted

Dr Hunt of Worcester asked for the privilege of making a brief reference to the report of his Subcommittee on the Adequacy of Medical Care He stated that it is important to know if the Society is willing to furnish the committee with financial backing for the necessary investigation in the event that the Federal Emergency Relief Administration will not supply funds He therefore made the motion that the Society authorize the Subcommittee to draw upon the Treasury to the extent of \$5,000 if such an amount be needed

Dr Mellus of Middlesex South referred to the fact that a budget was made last year and said that if this motion passed, the budget would be practically doubled He felt that the Council could carefully consider the matter before taking action.

Dr. Burnham of Essex North stated that he did not feel that the Council was working under satisfactory conditions He was sure that some of the men in the rear of the room could not hear what was being said and, as members of the Council, they were asked to vote without knowing the details From what he as one Councilor could get, it appeared that a house-to-

house survey was contemplated. He stated that it had already been done in a number of cities in the state by the State Department of Public Health. He said that Winchester and Lawrence had been selected among other communities and that the data are now available from the State Department of Public Health. It appeared that he was not in favor of spending \$5,000 for the work until he was more familiar with what it was intended to accomplish.

Dr. Tighe of Middlesex North did not believe that the Society could go before the public with an honest criticism of compulsory sickness insurance unless it was able to show that it was trying to find out what was wrong and that it intended to offer a remedy if one is needed. He stated that he regarded this campaign of education against compulsory sickness insurance as being tied up intimately with the investigation contemplated by Dr. Hunt's Subcommittee.

Dr. Hunt of Worcester answered Dr. Burnham's objection by stating that Dr. Lombard of the State Department of Public Health is working with the Subcommittee as adviser and statistician. Dr. Hunt said that if the State Department of Public Health had already made such a survey, Dr. Lombard would certainly have known about it and would have been guided by it in rendering advice. It appears that the survey which was made did not concern itself with the adequacy of medical care but was made in connection with another problem and that it would not serve the purpose of the Subcommittee.

Dr. Burnham was still inclined to feel that the amount asked for was excessive.

Dr. Mongan of Middlesex South stated that the survey is a serious thing and is the only way in which we can get reliable information. It is to be conducted under the supervision of the Society and it will cost money. He pointed out that California had spent \$25,000, Michigan had sent three men to England to study compulsory health insurance and that it cost the Society \$15,000. Is the Council willing to back its own proposition? If not, it can be stopped. No doctors will be paid for their part in the survey. They are giving their time and are offering their services without any thought of recompense. The profession desires to tell the people of Massachusetts what kind of medical service is obtainable here. He believes that the Society is fully able to spend the necessary funds.

Dr. Birnie of Hampden asked if in case the \$5,000 were voted would it not automatically go to the Committee on Membership and Finance. President Robey believed that it should go there but no provision had been made for it. Dr. Birnie thought that such a reference would be automatic and that the Council could not vote

any money unless the Committee on Membership and Finance had approved.

Dr. Butler asked Dr. Mongan if the State of California spent \$25,000 and the State of Michigan \$15,000, or if the State Medical Societies in these states spent such sums.

Dr. Mongan replied that the State Medical Societies spent the money and that, in addition to the \$25,000 spent in California by the Medical Society, one of the Federal organizations spent an additional \$60,000.

Dr. Burnham commented on the fact that it might be interesting to know the results of the money spent in the two states. California apparently spent \$25,000 and yet that is the only state in the forty-eight which has voted for compulsory health insurance. Michigan sent men abroad to make a study and spent money as indicated but the action of these men apparently did not bear the approval of the House of Delegates.

Dr. Butler spoke once more regarding appropriations by the Council. He stated that according to his understanding appropriations made by the Council are first submitted to the Committee on Membership and Finance for recommendation. In the past the practice also has been almost without exception that the various committees have been approached by the Chairman of the Committee on Membership and Finance asking for estimates of appropriations for the ensuing year. Based upon these inquiries the Committee on Membership and Finance has reported to the Council its recommendations for appropriations for the coming year. It seemed to him that at this time, when the budget has already been made out and appropriations have been properly made it is the Council's duty to keep within that budget. Additional appropriations of thousands of dollars would seriously disrupt the budgetary system of the Society.

President Robey then read Section 9 of Chapter IV of the By-Laws as follows:

"The Council shall vote the salaries of its officers, the appropriations for its officers and committees and such other appropriations as it may deem suitable except that every request for an extraordinary appropriation shall be first submitted to the Committee on Membership and Finance for a recommendation. The President shall decide what constitutes an extraordinary appropriation. The Council shall determine the amount of the annual assessment both for resident and for non-resident Fellows."

He stated that the chair can easily rule that this is an extraordinary appropriation which must then be submitted to the Committee. Therefore, the chair rules that this is an extraordinary appropriation and that it must be referred to the Committee on Membership and Finance.

Dr Bagnall of Essex North stated that if the Committee feels that this work should be done this summer and that if the money is needed, the Council may avail itself of the appropriation by authorizing the expenditure in case it meets with the approval of the Committee on Membership and Finance. He stated that if there is no motion before the house he would move that the Council take such action.

Dr Hunt withdrew his previous motion in view of Dr Bagnall's motion. Dr Bagnall's motion was duly seconded and was passed.

Dr Phippen of Essex South then presented the report of the special committee which had been appointed to consider the selection of a suitable person to assist the President and Secretary of the Society and the Editor of the *Journal*. (See Appendix No 16.) He then made the following motion:

"Moved that the President of the Massachusetts Medical Society be and hereby is empowered to appoint an Advisory Committee to consist of the President, Vice-President, Secretary, Treasurer, Managing Editor of the *Journal* and the Chairmen of the following committees: Committee of Arrangements, Committee on Publications, Committee on Membership and Finance, Committee on Ethics and Discipline, Committee on Medical Education and Medical Diplomas, Committee on State and National Legislation, Committee on Public Health, Committee on Malpractice Defense and the Committee on Permanent Home. This Committee shall meet at the call of the President or at such regular intervals as he shall designate."

Dr Birnie of Hampden asked if it was the desire of the Committee to include some other person from the Committee on State and National Legislation inasmuch as the Chairman of that Committee is the President of the Society.

Dr Phippen stated that the Committee had considered this matter and decided to leave the motion as it stands. The motion was duly seconded and was regularly passed.

Dr Phippen then presented a second motion as follows:

"Moved that the President be authorized to appoint, with the advice and consent of the Advisory Committee, an Executive Officer, who shall be employed upon a full time basis. He shall be under the jurisdiction jointly of the President, Secretary and Managing Editor of the *Journal* who shall also determine his duties."

This motion was duly seconded and passed.

Dr Phippen then moved that the report of the Committee be accepted and that the Committee be discharged. It was so voted.

There was no report from the Massachusetts Central Health Council.

Dr Bowers of Worcester commented on the authority which had been given for the employment of a general executive officer stating that no provision had been made for remuneration. He felt that this person should be brought into the organization as soon as possible, certainly this summer, and it would be advisable to give the Committee power to pay the necessary salary. Otherwise it would be necessary to defer action until the Council meets again.

Dr D N Blakely of Norfolk stated that according to his recollection some years ago the Council voted that the President be authorized, when he felt it advisable, to employ and direct the services of an assistant, and an appropriation has been made year by year since that time for such a salary. During the past year the Committee on Membership and Finance, in making up its recommendations for the budget, included the usual appropriation for the assistant to the President and in addition to that a contingent fund. Therefore, it appears that the salary was taken care of by the adoption of the budget last February. In case the amount provided for the assistant was not sufficient to employ a full-time person, adjustments might be made through the contingent fund.

Dr Lane of Norfolk asked for additional information from Dr Phippen. It was Dr Lane's understanding that the sum now paid from the appropriation for an executive assistant to the President and the advertising solicitor would be sufficient to cover the salary of the new executive. Dr Lane suggested that perhaps Dr Phippen would report the Committee's opinion on the approximate sum that would be involved.

Dr Phippen stated that the Committee did not go into the detail of the salary but that it believed that the appropriation for the President's assistant plus what could be saved in connection with the soliciting of advertising for the *Journal* would be sufficient.

The Acting Secretary stated that there might be a danger in setting a definite amount at this time since there would be a feeling that the maximum amount must be spent. He stated that at the time the Officers of the Society were the guests of the Committee, the matter was discussed but that it was felt that when a suitable person was found there would probably be enough in the budget to cover his salary. He felt that the type of person selected would naturally have a bearing upon the amount of salary to be paid. He suggested that since the Committee on Membership and Finance had carried an appropriation, the Officers and members of this Advisory Committee would be authorized to negotiate a proper salary with the individual they sought to appoint. Then the

Committee on Membership and Finance might be authorized to pay such a salary.

Dr Blakely said that he would put the matter a little differently. He believed that for the balance of the year the budget adopted would be adequate and that he agreed with the Acting Secretary that we have not yet gone far enough to know what will eventually be necessary. Since there is only a half year left and the appropriations were made for the full year including the contingent fund, there will be no trouble in meeting the salary when the proper individual is found.

Dr Lincoln Davis of Suffolk spoke for the Joint Committee Appointed From the Boston Medical Library and the Massachusetts Medical Society and stated that it would not be ready to report to the Council until the next meeting.

The President then announced that the Fellows in Springfield had offered the Society the opportunity of holding the next Annual Meeting in that city next June. It is the 300th anniversary of the settlement of Springfield, and the question was put as to whether the Society should accept the invitation. On motion of Dr Mongan and duly seconded, it was unanimously voted to hold the next Annual Meeting in Springfield.

The President then announced the Standing Committees for the coming year which were as follows:

COMMITTEE OF ARRANGEMENTS

W. R. Morrison *Chairman* Horatio Rogers W. S. Burrage, R. P. Stetson Augustus Thorndike, Jr.

COMMITTEE ON PUBLICATIONS

H. I. Lee *Chairman* Homer Gage R. B. Osgood R. M. Smith F. H. Lehey

COMMITTEE ON MEMBERSHIP AND FINANCE

D. N. Blakely *Chairman* G. C. Caner J. E. Fish, H. F. Newton H. Q. Gallups.

COMMITTEE ON ETHICS AND DISCIPLINE

David Cheever *Chairman* W. D. Ruston S. F. McKeen A. C. Smith, R. L. DeNormandie.

COMMITTEE ON MEDICAL EDUCATION AND MEDICAL DIPLOMAS

Reginald Fitz, *Chairman* C. H. Lawrence C. A. Sparrow E. S. Calderwood A. S. Begg

COMMITTEE ON STATE AND NATIONAL LEGISLATION

Charles E. Mongan, *Chairman* F. E. Jones A. W. Marsh, A. S. Begg D. L. Lionberger

COMMITTEE ON PUBLIC HEALTH

Dwight G. Hara, *Chairman* G. N. Hoeftel G. D. Henderson S. C. Dalrymple, H. L. Lombard

COMMITTEE ON MALPRACTICE DEFENSE

F. G. Balch *Chairman* E. D. Gardner, F. B. Sweet, R. P. Watkins A. W. Allen.

COMMITTEE ON PERMANENT HOME

R. B. Greenough *Chairman* C. G. Mixer J. M. Birnie, C. S. Butler E. C. Miller

The President stated that the Special Committees, except those whose duties have terminated, will be continued as committees of progress.

Dr Lane of Norfolk pointed out that a recommendation had been made by a committee and accepted by the Council to the effect that there should be a representative of the Massachusetts Medical Society who for all practical purposes would act as the press representative of the Society. Since no one had been appointed he nominated Dr David Cheever. The motion was duly seconded and passed.

Dr DeNormandie of Suffolk then asked permission to read a resolution before the Council (See Appendix No. 17). After an extended discussion it was finally voted on motion of Dr Walcott of Middlesex South that the resolution be laid on the table.

Dr Conrad Wesselhoeft of Suffolk presented a resolution which was duly seconded and passed after considerable favorable comment (See Appendix No. 18).

The Acting Secretary announced that the District Public Relations Committees were asked to attend a meeting at 5:00 o'clock in the Salle Moderne.

There being no other business, the meeting adjourned at 3:53 P.M.

ALEXANDER S. BEGG,
Acting Secretary

APPENDIX TO THE PROCEEDINGS OF THE COUNCIL

APPENDIX NO. 1

REPORT OF THE COMMITTEE ON MEMBERSHIP AND FINANCE

This Committee recommends

1. That the following named eight Fellows be allowed to retire under the provisions of Chapter I, Section 6 of the By-Laws

1. Bailey George Guy Ipswich.
2. Cobb, Albert Crocker Marion
3. Griensard George Augustus Fitchburg with remission of dues, 1935
4. Herrick, Joseph Thomas, Springfield with remission of dues, 1935
5. Morris George Patrick, South Boston, with remission of dues 1935
6. Norton Eben Carver North Chatham with remission of dues, 1935
7. Perkins Archie Elmer Fitchburg, with remission of dues, 1935
8. Stowell Fred Austin Newburyport.

2. That the dues of the following named four Fellows be remitted under the provisions of Chapter I Section 6 of the By-Laws

1. De Wolfe, Henry Charles Mitchell Malden, 1934
2. Dnbols, Eoline Church, Springfield 1932 1933 1934 1935

3 Kushner, Israel Louis, Somerville, 1931, 1932, 1933

4 Ryan, Sylvester Edward, Longmeadow, 1932, 1933 in part

3 That the following named five Fellows be allowed to resign under the provisions of Chapter I, Section 7, of the By Laws

1. Allen, George Edgar, Montpelier, Vt, with remission of dues, 1935

2 Boynton, Lyman Crowell, Rochester, N Y with remission of dues, 1935

3 Canzanelli Attilio, Medford, with remission of dues, 1935

4 Smith, Clara Lottman, Providence, R. I, with remission of dues, 1935

5 Streeter, John Frank, Springfield

4 That the following named five Fellows be deprived of the privileges of Fellowship under the provisions of Chapter I, Section 8, Clause (a) of the By Laws

1 Gilbert, Meyer Manus, Lynn

2 Lilyestrom, Sanfrey Matthew, Worcester

3 Nolen, Walter Freeman, Walpole

4 Savage, Ross Elliot, Sharon

5 Sinclitico, Joseph A, Lawrence

5 That the following named six Fellows be allowed to change their membership from one District Society to another without change of legal residence, under the provisions of Chapter III, Section 3, of the By Laws

One from Middlesex North to Middlesex East

1 Sims, Frederick Robertson, Bedford

One from Norfolk to Essex South

1 Tadgell, Henry Allen, Wrentham

Three from Norfolk to Suffolk.

1 Marble, Alexander, Brookline

2 Walcott, Charles Folsom Brookline

3 Zollinger, Robert Milton, Brookline

One from Norfolk South to Suffolk

1 Howe, Henry Furbush, Cohasset

DAVID N BLAKELY, *Chairman*

June 4 1935

APPENDIX NO 2

REPORT OF THE TREASURER

As the fiscal year of the Society is from January 1st to December 31st, the full years report of the Treasurer was offered to the Council at its February meeting. At this time therefore, the Treasurer offers an interim report, to June, 1935

Receipts of annual dues by District Treasurers, and forwarded to the Treasurer of the Society, are \$1500 greater than were received in the corresponding period of 1934. This is a very encouraging result, because, if you will recall, the total of annual dues received in all of 1934 was the largest such amount ever received by the Society.

Income from securities in "General Fund" is, however, slightly less than in 1934 for the corresponding period. This is not because of defaults in interest on securities held, but due rather to the low income rates to be obtained now from purchases of high grade bonds in which funds of the Society are invested. In general the market prices of our bond securities, during this year, have been well maintained. Some prices have slightly decreased, some, increased. But many of our securities are selling at their highest prices during the past thirty years.

The Treasurer has invested part of the excess cash in short term bonds, to bring in some income.

Expenses of the Society, now that Committees have widened their activities and increased their interest in work as well as in results, are greater this year than for the corresponding period of 1934. No extraordinary expense has thus far occurred.

The amount of routine work going through the Treasurer's office, during the past year, has increased considerably. This is the result of greater activities of Committees, as well as the natural result of the needs of the growing Fellowship of our Society.

CHARLES S BUTLER *Treasurer*

June 4, 1935

APPENDIX NO 3

REPORT OF THE COMMITTEE ON ETHICS AND DISCIPLINE

Like poverty and taxes, the problems of ethical behavior arising among the members of a great professional organization are always with us, and do not vary much in kind from year to year. Your committee has held six formal and many informal meetings, and the Chairman has had numberless personal conferences with individuals and groups. Formal hearings have been accorded to four Fellows. The actual discipline invoked has included reference of one offense to a Board of Trial, a demand for resignation from the Society for falsification of financial accounts and withholding from a brother practitioner a fee collected for him, a deprivation of privileges of Fellowship (in conjunction with the Committee on Membership and Finance, under Chapter I, Section 8—Clause C of the By Laws) for complicity in an abortion, of which the accused was found guilty in a court of law, a recommendation to the President of a severe admonition for a Fellow who had been disciplined by the Board of Registration for an offense which for certain reasons it was impossible for the Committee itself to investigate.

The Board of Trial was called by the President on request of the Committee to try a Fellow on a charge of conspiracy to defraud an insurance company. This matter was referred for consideration by the Society at the annual meeting the following day.

The Committee, without intending to take cognizance of alleged exorbitant fees, supervision of which is not expressly provided for in the Code of Ethics, believes that it is expedient at times to give some consideration to the numerous complaints which it receives. The Committee is of the opinion that the charging of very large fees which seem to the patient very disproportionate to the services rendered is one of the factors which incline the public mind more and more toward State or Socialized Medicine. It believes that in very few instances is it for the best interests of either doctor or profession for a collection agency to attach the bank account, tools of trade or other personal effects of a debtor patient. It believes that often this is done without the knowledge or consent of the physician. It believes that a fee so obtained is too dearly won. It has tried through the exercise of good offices to compromise and adjust some of these disputes, with reasonable satisfaction to both parties, it must be admitted that no brilliant success has crowned its efforts.

Publicity, which advertises the professional doings and alleged attainments of physicians in the lay press, on the air and in the market place, continues to be a sore, annoying and controversial point. The members of the Council are too familiar with the situation to require an extended discussion of it here.

The recent cases of our Vice-President, who in no way personally responsible saw a successful surgical operation broadcast and blazoned forth over the world in newspaper and film to an extent which it is reliably estimated would have cost five and one-half million dollars if paid for at advertising rates is an example in point. In these cases it is usually the policy of the Committee to tell the Fellow involved that the publicity attaching to him has caused criticism to receive from him the assurance that he was in no way responsible for it and if the occasion seems to require it, to ask him to make a statement to that effect in the *Journal* at the same time testifying to his sympathy with the accepted standards of the Society. Usually an incident of this kind is followed by letters to the Committee, about equally divided between scornful censure of our feeble attempts and warm praise for our broadminded tolerance and judgment. Evidently one cannot please all the people all the time.

As in former years the Committee feels that any usefulness which it may have is as a permanent body which exists to interpret the accepted standards of ethical behavior of this Society to younger members.

DAVID CHEEVER, *Chairman*

APPENDIX NO 4

REPORT OF THE COMMITTEE ON MEDICAL EDUCATION AND MEDICAL DIPLOMAS

During the past year the Committee on Medical Education and Medical Diplomas has held several meetings. In accordance with directions from the Council the Committee has chiefly occupied itself with assisting at the introducing of a Bill before the Legislature to improve the Massachusetts Medical Licensure Act. In this undertaking the Committee has been materially helped by the devotion of President Robey and Acting Secretary Bege. The upshot of the matter has been that House Bill 156 our original bill was given leave to withdraw and in its place was substituted House Bill 2054 which advocates the appointment of an unpaid special commission to study the question of medical educational conditions in the Commonwealth and to report the results of this study to the General Court before the first of December. The fate of the bill is still pending.

The Committee has examined a larger number of candidates from unrecognized Medical Colleges than in previous years. The problem as to whether such candidates tend to make desirable members or not remains unsolved.

From the point of view of our Committee the situation has become complicated during the past year not only by the laxness of the present Medical Licensure Act of Massachusetts but also by the fact that many hospitals in order to maintain recognition as hospitals and particularly as hospitals qualified to train Interns have tightened up on their Staff appointments and have made it increasingly difficult for men not members of the Massachusetts Medical Society to obtain hospital privileges. On this account considerable pressure has been placed on our Committee to recognize the diplomas of men who desire to become members solely because in so doing they can be made staff members of various hospitals. The correct attitude for the Society to adopt on the matter is a difficult one to decide. It seems to us that if the Massachusetts Medical Society becomes less strict in its qualifications for membership this will reflect upon the hospital situation in Massachusetts. While hospitals may legitimately increase their staff membership yet unless rigid standards are upheld a situation may easily arise that is detrimental to the public welfare. On

the other hand our Committee does not wish to keep out of the Society any doctors who might make useful members.

We badly need guidance on these matters. At the February meeting of the Council our Committee asked the President to appoint a sub-committee to study these problems. We await the results of their deliberations with great eagerness.

During the past year 244 new members were admitted as Fellows of the Society. Of these nine per cent were graduates of unrecognized schools a slightly lower proportion than for several years.

Through the generosity of the Society an annual prize of fifty dollars has been offered for the best case report by any intern holding a rotating internship in any of the Massachusetts hospitals approved for intern training by the American Medical Association. From the papers submitted this year the prize was awarded to Dr Joseph C. Edwards of the Springfield Hospital for his report dealing with an unusual case of bronchiogenic carcinoma. The Committee hopes that an annual competition of this sort will act as a stimulus toward improving the work of interns who are being educated in Massachusetts.

The Committee has continued with its studies of intern training and hopes eventually to be so informed as to have an authoritative opinion regarding the kind of intern training that is available in this state and how our Internships may be improved.

Finally the Committee has sponsored an "Educational Number" of The *New England Journal of Medicine* in conjunction with the Editorial Staff of that *Journal*. This number will soon be forthcoming and will include a group of papers dealing with various educational problems that confront the Society. It is hoped that an annual number of this character may stimulate and interest all doctors who are seriously concerned with improving medical education in Massachusetts whether in their capacities as teachers in Medical Schools as Staff Members of Hospitals which train interns or as readers of papers before local medical societies.

Respectfully submitted

C A SPARROW
E S CALDERWOOD
A S BEGE

REGINALD FITZ, *Chairman*

APPENDIX NO 5

REPORT OF THE COMMITTEE ON STATE AND NATIONAL LEGISLATION

The legislative work this year has been extremely heavy. We began in December by studying a considerable number of bills that had already been filed at the State House and the delay in the organization of the Senate gave us a chance to study many more that were filed just about the closing date. Altogether somewhere in this neighborhood of 100 bills were studied but the list was reduced by elimination and finally we had about 40 bills under consideration. After some further reduction the members of the Society were notified from time to time concerning the status of these bills. In the Legislature at the present time there are two bills that are of particular concern to the profession.

House Bill 1157 has been brought to your attention through the medium of cards that were handed out to you at the time of registration. This is the chiropractor bill, which was reported favorably by the Committee on Public Health. Someone said today that that was reported unanimously. This is not true. There were five members dissenting from favorable

report, and I think you ought to know who those dissenters are. The Chairman, Senator Cole, Senator Miles, Representative Theberge, Representative Ashe, and Representative Murphy, five out of approximately 15 on the Committee reporting adversely. But the bill has been introduced into the House and has been referred to the Committee on Ways and Means acting jointly with the similar Committee of the Senate. Every effort naturally should be made to defeat this bill. There will be an interesting editorial in the next issue of the *Journal* which deals with this subject. Those of you who saw the recent editorial in the *Herald* will have some idea of how some of the laity feel about this matter. The same points should be emphasized in connection with it, that the enactment of such a bill would tend to reduce the single standard by which we now operate and would be contrary to the public interest.

The other bill on which we are still working is House 2054, a resolution substituted for House 756, which was given leave to withdraw. This resolution, as Dr. Fitz has pointed out, calls for a study during the recess by an unpaid commission, which is to report with recommendations at the next annual meeting of the Great and General Court. The commission is described in the bill, and those of you who are interested may obtain at the registration desk a copy of the bill with the editorial that was published in the *Journal* about two weeks ago. This is an important bill and should be supported. The cards ask you to see, phone or write your State Senator and Representative at once and get your friends to do likewise.

The Committee's work has been pretty extensive. We have attended many hearings at the State House and there has been a great deal of correspondence. We have made free use of different organizations throughout the State. We have bothered the members of the Public Relations Committee. They can never tell when they will be waked up and a night letter thrust into their hands, something more to do in an approach to the Legislature. It is hoped that we may be able to complete our organization during the coming year, since we have discovered as we worked at the State House this year that other groups are definitely organized, and it appears that to be effective our Society must do likewise.

A S BEGG, *Acting Secretary*

APPENDIX NO 6

REPORT OF THE COMMITTEE ON PUBLIC HEALTH

The Committee on Public Health, with its Subcommittee on Public Education has continued to cooperate with the State Department of Public Health in the broadcasting of popular medicine. This cooperation was initiated by vote of the Council five years ago. In order to secure the broadcasting facilities it has been necessary to mention the names of the broadcasters. Thus there has been granted a sanction for radio publicity which has never been granted to the press. We have repeatedly pointed out that this constitutes what might be called discrimination in our choice of publicity mediums.

Whether this is in fact discrimination, or a compromise necessitated by divided opinion on the whole subject, is hard to say. Five years ago the introduction of a broadcaster by name was considered the limit to which the Medical Society should go in publicizing its individual Fellows. Today a medical meeting seems to have become sufficient reason for hiring a publicity agent to arrange for broadcasts, photographers, and the release of copy to the press.

Last fall many of us were startled to find ourselves entertaining a group whose publicity had preceded them into every Middlesex village and farm.

The charge given to us five years ago was "to procure the preparation of material for the daily press and for radio broadcasts on medical subjects, and to assume responsibility therefor in the name of the Massachusetts Medical Society." If the Society wishes them to do so this Committee and the State Department of Health can drive six white horses as well as anybody else. We have felt, however, that conservatism would more appropriately represent our Puritan ancestry. Perhaps it was in our blood to have published a Communication entitled "The Hazards of Publicity." This appeared in the *New England Journal of Medicine* of March 21, 1935, and was distributed to the Council at its last meeting. It was called a Communication, not a Report, in order that it might not imply opinion or action beyond that of the Committee itself. Shortly thereafter Dr. Iago Galdston, Executive Secretary of the Medical Information Bureau of the New York Academy of Medicine, submitted some Comments which were published, at the suggestion of the Committee, in the *Journal* of May 2, 1935. Reprints of these Comments are being distributed to the members of the Council today.

The Committee earnestly hopes that our Fellows are giving thought to these trends of medical publicity. Although it has largely refrained from announcing the discovery of new cures, sera and anesthetics, it would be as happy to follow the Joneses as anyone else provided they are members of the Massachusetts Medical Society in good standing.

Respectfully submitted,

DWIGHT O'HARA, *Chairman*

APPENDIX NO 7

REPORT OF THE COMMITTEE ON MALPRACTICE DEFENSE

The Malpractice Defense Committee has had a very uneventful year. There were pending in the hands of Palmer, Dodge, Barstow, Wilkins and Davis at our last report eleven cases. During the year, we turned over three more. Two of our cases were disposed of, one being dismissed under a rule of the court for lack of prosecution and in the other the plaintiff was non-suited after the case had been sent out to a session for trial. There are at the present time twelve cases pending.

One new law has been passed by the Legislature which concerns malpractice suits, House Bill No. 595. This is an act to provide for the advancement of cases for speedy trial in the superior court. It provides that in all actions of contract or tort for malpractice error, or mistake against physicians, surgeons, etc. pending in the superior court now or at any time, the court shall at the request of any party to the proceeding advance the same so that it may be heard and determined with as little delay as possible.

This does away with the long delay in malpractice defence suits and ought to be a great relief to the situation. The bill was not pushed by your Committee, nor did I hear of it until it had been passed.

* FRANKLIN G BALCH, *Chairman*,
ARTHUR W ALLEN, *Secretary*

May 23, 1935

APPENDIX NO 8

REPORT OF THE COMMITTEE ON PERMANENT HOME

The Committee on Permanent Home of the Massachusetts Medical Society made a report at the spe-

cial meeting of the Council in April in regard to the renewal of the note of the Boston Medical Library which came due on April 1 1935

In conference with the Treasurer of the Massachusetts Medical Society and the officers of the Library, this note was renewed for a period of one year from April 1 1935 at 4% per cent and a payment on the capital was made of \$203.00 reducing the note to \$24500 00

It is understood that the Library will be in a position to reduce the principal materially on or before April 1 1936

Respectfully submitted

APPENDIX NO 3

REPORT OF THE COMMITTEE FOR THE STUDY OF RHEUMATISM AND ALLIED DISEASES IN MASSACHUSETTS

The following is the report of the first meeting of the Committee for the Study of Rheumatism and Allied Diseases in Massachusetts. The members present unanimously agreed to the following

I. The Committee is convinced that the problem of chronic rheumatism demands solution

II. The Committee can visualize no method of beginning to meet this need which does not provide a hospital of approximately two hundred and fifty beds suitably equipped and staffed to care for patients with chronic rheumatism. Such an institution must be either privately endowed or under the supervision of the State Department of Public Health.

III. Such an institution might be expected to serve the physicians and people of the State of Massachusetts by making possible

A. A complete and correct diagnosis

B. The discovery of the probable underlying cause of the particular type of chronic rheumatism existing

C. The initiation of the necessary appropriate hospital treatment.

D. The planning of a future régime and follow-up

E. The return of all patients to their private physicians it being understood that all patients are sent to such an institution by the local physician. It is hoped that the physicians will feel free to return any or all of their patients for subsequent periods of observation treatment and further suggestions

IV. Such an institution should serve as an educational clinic where both physicians and patients might obtain information as to the best methods of controlling chronic rheumatism.

WALTER BAUER, *Secretary*

APPENDIX NO 10

REPORT OF THE COMMITTEE ON CANCER

The Committee on Cancer of the Massachusetts Medical Society has lost two of its five members during the past year by the death of Dr George F. Martin and Dr George H. Bigelow

At the meeting of the Council in February Dr E. M. Daland was appointed to take the place of Dr Martin.

On May 22 1934 this Committee assumed the responsibility for arrangement of a clinic on cancer for the members of the staffs of the state-aided cancer clinics in Massachusetts. This clinic was given in the morning at the Massachusetts General Hospital and in the afternoon at the Palmer Memorial Hospital with an attendance of about forty five members of the Society

Respectfully submitted

REPORT OF THE COMMITTEE ON POSTGRADUATE INSTRUCTION

The Committee on Postgraduate Instruction wishes to report that the second annual series of extension courses was completed on May 31 1935. The Committee wishes to acknowledge the splendid cooperation from all the districts and especially wishes to thank the district chairmen for the great amount of detailed work which they have handled to make possible the success of the courses in their respective districts

The extension courses were given in the following places

District	Attendance
<i>Barnstable</i>	
Hyannis	3
<i>Berkshire</i>	
Pittsfield	5
<i>Bristol North</i>	
Attleboro	1
Taunton	1
<i>Bristol South</i>	
Fall River	14

Worcester North

Ayer	16
Fitchburg	29

Total No Sessions—240 Total Attendance—834

There were one hundred and thirty six instructors on the faculty. The following list gives the names of the instructors with their respective subjects. The Committee wishes to express the thanks of the Society to this devoted group of instructors who have given freely of their time to make the course a success.

On May 22 the General Committee met and voted to continue the course next year. A program has been prepared and was presented to the district chairmen at a meeting held in Boston yesterday. As soon as the courses have been chosen the faculty will be assigned for each district. This will give the district chairmen ample time to advertise the course before autumn.

Respectfully submitted,

APPENDIX NO 12

COMMITTEE ON PUBLIC RELATIONS

REPORT OF THE SUB-COMMITTEE ON
ADEQUACY OF MEDICAL CARE

To this sub-committee was delegated the task of determining whether the population of Massachusetts is being adequately served by the medical profession, and to what extent medical charity is abused by hospitals and other agencies. The methods for pursuing this task were prescribed by the committee and were three in number, as follows: (1) A questionnaire to be sent to all members of the Society; (2) Hearings to be held in the various districts of the state, conducted by the adjunct Public Relations Committees in each district society under the direction of the member of the State Committee from the particular district; (3) A survey of a cross section of the population through a house to house canvass by paid workers, to glean unbiased information from the people themselves as to whether there is lack of adequate medical care.

The work of preparation has been very considerable and progress hampered by our lack of experience in the conduct of such researches, the necessity for committee agreement, and finally a lack of funds to defray the costs of such a program.

This last difficulty was alleviated in part by vote of the Council at the February meeting at which time one thousand dollars was appropriated for the purpose of the survey.

The first phase of the work has been accomplished so far as this sub-committee's function goes. The results are available in detail herewith and will be summarized presently.

The second phase was deferred because of objections on the part of some of the local Public Relations Committees that they did not feel competent for the task, and doubt as to how much basic and reliable information could be secured by the method at this stage in the organization of the local committees.

The third phase has been carefully planned the cooperation of the State Department of Public Health secured and that of the Federal Emergency Relief Administration asked. The reasons for seeking help from the State Department of Public Health were two. We thereby secured (a) the technical advice and help of Dr. Herbert L. Lombard, statistician extraordinary and (b) the influence of affiliation with a state department to bear upon the F.E.R.A. The reasons for seeking aid from the F.E.R.A. were (1) that a calculation of the cost of an efficient canvass of 1 per cent of the population figured about \$7000 whereas our appropriation was \$1000. (2) Inasmuch as it is a part of the duty of the F.E.R.A. to provide employment for certain white-collar workers it was thought to be a legitimate and proper means to an end of value to the public quite as much as to the doctors.

A copy of the plan submitted is available herewith. It has been filed with the F.E.R.A. administration at Worcester after an encouraging interview with Mr. Conrad Hobbs of the Boston office. The reply has not yet been received. An alternate plan should be available if the project is not approved by F.E.R.A. It can be done by employing medical and other students during the summer if the society will appropriate the necessary funds for use if and as needed.

Reverting now to the returns from the Questionnaire I will briefly summarize and interpret the information gained. Of 4600 blanks sent to the members through the district societies 1121 were returned up to April 26 1935 21 of which were not filled out for reasons which were courteously explained leaving 1100 replies available for analysis. Why seventy-five per cent of our membership failed to cooperate in this effort in behalf of their own interests is a question of psychology upon which I need not now dwell. To the 1100 who painstakingly filled out and returned their blanks the committee wishes to express its hearty appreciation and thanks.

Section I of the Questionnaire deals with adequacy of medical care and is subdivided into its technical adequacy and its economic availability.

SECTION I

A1 Of 1053 answers only six admitted any lack of doctors and thirty-four said there were too many.

A2 Of 1083 answers regarding hospital facilities only twenty-four admitted lack of whom qualified their answers to the effect that the facilities were economically inaccessible while twenty-seven felt that there was an over supply.

A3 As to the availability of specialists the replies were similar although on this question there were more blanks one hundred and eighty-two as to the first class and 137 as to the second. According to 872 there are plenty seven, there are too many eleven that they are sometimes economically inaccessible twenty

two think there are not enough, certain specialties being less available than others. Nine hundred and twenty-eight report no loss of time in securing the service of specialists while fifteen find that such loss exists.

A4 The situation as to nursing service is similar although a bit more emphatic as to no lack of either visiting or private nurses. Lack of so-called domestic nurses and limitations due to the cost of nursing service are suggested. Eleven hundred and nine find plenty of visiting nurses as against sixteen that do not. Fifteen think there is an over-supply of visiting and seventy-five think the same of private nurses.

In the section calling for remarks there is little elaboration of the answers bearing upon number and distribution of doctors shown above. Several points on the present tendency toward an over-supply of doctors especially those from sub-standard schools who by reason of stricter laws in other states gravitate to Massachusetts and become a menace to ethical as well as technical standards of service. Too many doctors in cities and an excess of specialists in relation to the number of people who can afford to pay the specialists' prices is suggested but not sustained by figures. As to economic inaccessibility of hospitals and specialists it is pointed out that people do not appreciate the provisions of hospitals for free service to the poor nor the willingness of specialists to mitigate their charges for deserving patients of the low income groups. The duty of correcting the over-supply of both doctors and nurses is placed upon the schools by one respondent.

But one instance each of suffering from lack of medical hospital and nursing care is reported.

Section B

B1 This section deals with the lack of purchasing power as a reason for inadequate medical care. Doctors were asked to estimate the percentage of inadequacy of medical and hospital care because of inability to pay. One hundred and twelve attempted to do so and the mean of their estimates is twenty per cent. One hundred and eighty-nine answer "YES" to the question "Is there a considerable group of people in your community which has failed to receive adequate medical attention because of inability to pay the doctors and hospital charges?" Five admit the possibility while 304 reply "No" twenty-eight of whom qualify their answers by showing that other causes than lack of purchasing power explain much of the failure to receive adequate care. Ignorance, carelessness and procrastination on the part of patients and parents are most prevalent. Twenty-three per cent of the replies show inadequacy of care on this account.

B-1-a. Sub-section deals with the untoward results of delay in seeking medical aid because of inability to pay. One hundred and fifty-six have knowledge of such cases and fifty-four think such exist but are rare. Eight hundred and thirty-four know of no such cases and nineteen say "NO" but qualify it.

Among the comments delay in obtaining aid for acute appendicitis, other specialist services and procrastination in minor cases are mentioned. Several express the opinion that the poor and the rich do not need to delay while the self-respecting middle class suffers most. Twenty per cent of the replies show inadequacy on this account.

B-1-h Sub-section touches on neglect of treat

ment or continuing care Thirteen plus per cent find that it exists

B1-c Sub-section regards retardation of recovery by lack of diet, drugs or appliances Thirty think there is such retardation

B1-d Sub-section refers to suffering or retardation of recovery from lack of nursing care Twenty-four per cent of those who replied indicated an opinion that varying degrees of suffering and retardation exist.

SUMMARY OF SECTION I

It is shown that while there is practically no recognized lack of available doctors and specialists, hospitals and nurses, it is the opinion of 22.8 per cent of the respondents that suffering does exist because people neglect to obtain available service by reason of economic disability

SECTION II—ABUSES OF MEDICAL CHARITY

There is nearly universal recognition of encroachments by institutions, societies, health departments, private commercial enterprises and nursing associations Four hundred and eighty-six replies particularize 1013 times as to ways in which medical charity is exploited Ability to draw the line between coöperation with and exploitation of the medical profession is generally lacking All, as essential parts of health service, naturally overlap when 100 per cent good will exists With commercial incentive in many of these organizations and with practice on a competitive rather than a cooperative basis, such overstepping of one upon the interests of the other seems inherent in the system

ANALYSIS OF REPLIES TO SECTION II

A—Abuses by the People

1 To what extent are you the victim of persons who can afford to pay but neglect to do so or who misrepresent their economic situation in order to receive free or low rate service?

Nine hundred and twenty-three admit varying degrees of this type of abuse, 316 estimate it in terms of percentage, of which the mean estimate is forty-four per cent, 254 say "SMALL" or "MODERATE" while 250 say "LARGE", 103 say "YES" without qualification

2 Do people who are not fit subjects for charity use hospital facilities which rightfully belong to the less fortunate? Seven hundred and forty-three reply in the affirmative, 119 in the negative, 170 qualify their affirmative opinion, sixty-eight do not answer or are non-committal

Among the qualifications, appreciation is not lacking of the difficulty encountered by hospitals in eliminating those who improperly seek medical charity Some consider this the real cause of the economic plight of the doctors City employees, especially in Boston, are named as particular offenders in this respect Adequate social service with credit bureaus as maintained by department stores is suggested as a remedy

Persons able to pay know that free patients in hospitals have good doctors, good food and nursing service They cannot understand why they should not benefit by a service which they help to maintain by taxes

B—Abuses by Hospitals

B1-a Sub-section deals with abuse by permitting patients able to pay to be treated on free service wards Two hundred and eighty-four reply in the negative that hospitals give no such

permission Thirty-six qualify negative answers. Five hundred and eighty-seven reply in the affirmative, forty-two qualify it as rare and forty-two qualify it otherwise One hundred and nine give no information

B1-b Discrimination by permitting private nursing care for persons who do not pay the doctor This is admitted by 437, denied by 353, minimized by forty, denied with qualifications by fifty-two and admitted with qualifications by sixty-one One hundred and fifty-six give no information

B2-a Detrimental interference with work of physicians? Such is denied by 457, denied with qualifications by sixteen It is affirmed by 449, thought rare by thirty-nine, and qualified in the affirmative by forty-four No information is given in ninety-four replies

B2-b Detrimental to patients? Only 104 replied specifically to this item, seventeen of which were affirmative Because both items were included in one question, the unqualified answers in B2-a must be interpreted as relating to both physicians and patients

B-3 Other ways in which medical charity is exploited? Two hundred and eighty-four were disinclined to answer Eighteen did not know, 308 answered "NO" to the question as against fourteen answering "YES" Four hundred and eighty-six were in the affirmative and particularized their meanings to the extent of 1013 specifications These specifications relate to

(a) Private enterprises Clinics of many types, hospitals in ways mentioned in 4a above and twelve other counts, nursing, district, Red Cross, community and industrial, social workers, and miscellaneous charity and character building organizations

(b) Public enterprises Health department activities relating to clinics, hospitals and prophylactic organizations, municipal welfare activities, especially work of city physicians and hospitals under political domination and medical care under ERA.

(c) Outside Agencies Dealing in advice, remedies, insurance coöperative societies, contract services, free and low rate laboratory services (x-ray), advice from doctors not registered in Massachusetts, etc

(d) Within Medical Profession Monopoly by influential leaders in the profession, referred work unpaid, assistants not allowed to collect for services and specialist fees

REMEDIES SUGGESTED

In formulating remedies it is well that we keep clearly in mind the distinction between civic agencies and institutions organized for general welfare, appreciative of the part played by medical service therein, and those other agencies operated for profit which tend to reduce the medical profession to a plane of dependency of which Industrial Accident Insurers are outstanding examples

There are numerous suggestions as to what can be done by the Medical Society in relation to these abuses Elimination of unfair practices among doctors themselves, promotion of better business methods and education of the people to regard the employment of a physician as a business transaction are suggested Many feel that we could compel hospitals to weed out more effectively the clinic patients who might pay reasonable fees to private practitioners and also help the physicians by greater care as to who is admitted to the wards on free service These many criticisms and suggestions bring

up the question "Is the Massachusetts Medical Society ready to define conditions under which its members may do charity work in hospitals and compel their observance under penalty of loss of fellowship?"

Your committee is not now prepared to recommend such a course

Pay for staff doctors in publicly maintained hospitals and clinics is suggested by several. Your committee feels that were such a plan adopted the hospitals would no longer be under any ethical restraints but would frankly compete with the practitioners and have every advantage on their side.

Further consideration and study of abuses of medical charity so far as it relates to hospitals is now a function of the Sub-Committee on Hospital Relations

SECTION III—THE DOCTOR'S BURDEN

A. Service Rendered Individuals

A.1. Without pay Of the 100 who replied but fifty two do not render such service forty-nine did not answer fourteen do not know and five are not in active practice. The remaining 980 or ninety per cent, render service to individuals without pay. Two hundred and forty-two estimate the amount in general terms large moderate, small while 599 express it in terms of percentage of which twenty-five per cent is the mean.

A.2. At reduced rates Here the figures are much the same. Nine hundred and thirty or eighty-five per cent, give services at reduced rates and of 537 who estimate in terms of percentage, the mean is thirty-five per cent. Some give special reasons for reductions such as the known ability of patients to pay discounts on large bills, patients of long standing who are in reduced circumstances and other professional persons.

B. Unpaid Service to Hospitals and Clinics

B.1. As to amount of time given Two hundred and eighty-five give none ninety-three do not answer five do not know how much time ten are on consulting staffs part pay jobs etc leaving 717 thirty-five per cent, who give such services. Five hundred and sixty-five give a total amount of 153,246 hours per year or an average of 399 hours each. Seventy estimate time given in terms of percentage of which the mean is forty per cent. The balance (72) express it in general terms large small variable.

B.2. Number of patients treated Only 557 or fifty-six per cent attempt to estimate of whom 129 express themselves in general terms while 428 state numbers of patients specifically

SECTION IV

SHARE OF BURDEN BORNE BY COMMUNITIES COOPERATION BY COMMUNITIES IN CARE OF SICK

A. By paying doctors on fee basis. Sixteen report that their communities give full pay eleven report a rare fee twenty-eight receive pay from lodges and 141 do not specify the source of pay given.

B. By contract. Five hundred and eighty-eight report community cooperation by contracts from various sources

C. From work in free clinics in which doctors are paid, payment by public agencies is known by 246 doctors. Payment by private agencies is known by 185

D. Cooperation by furnishing nursing service. Five hundred and seventy-four acknowledge such help. Many speak of the cooperation of district nurses in highest terms

SECTION V

PATIENTS OF REDUCED INCOME BUT NOT YET INDIGENT ARE VARIOUSLY AIDED

A. Source. Seven hundred and fifty-one give no answer or do not know. One hundred count them as part of the doctors' burden forty-one the doctors' burden plus free agencies. Nine think they get no aid and fifty-five think that public and private welfare agencies help them.

B. Community help to medical care. Four hundred and seventy-one are unable to answer. Five think no care is received while 258 hold that both the indigent and near indigent are helped. Three hundred and thirty-four say that only the indigent are aided.

COMMENT ON SECTION III AND IV

The contribution of physicians in time, effort and substance toward carrying the burden of medical care for the indigent in hospitals and the near indigent in office and home has been enormous. (Eleven hundred doctors give the amounts shown above. What would have been the figures if the other 3500 had replied to the questionnaire?) The communities have been backward in recognizing the unfairness of this situation and in most instances have failed to include adequate medical care in their provisions for relief. Slow to realize the wisdom of investment in preventive effort, Welfare Boards have generally made reduction to the plane of indigency the essential for relief.

A system whereby the costs of medical care for the victims of the depression are spread upon the community without breaking the relation of families to their physicians should be universal and uniform throughout the State. Doctors can be relied upon to meet the communities half way as has been shown in certain parts of the state where this enlightened plan has been tried. It is recommended that the Society concern itself in extending the plan now in effect in Franklin County to the rest of the State.

SECTION VI

DOCTORS' INCOMES IN 1934 AS COMPARED WITH 1930?

Eighty-two reported small to considerable increases which are explained by change from general practice to specialties or young men who have started since 1930.

Seventy-five report no change and include salaried men and those whose work has increased without corresponding increases in earnings. The mean of increases is sixty-two per cent.

Six hundred and seventy-two or sixty-one per cent report decreases some of which are specifically mentioned and vary from \$100 to \$15,000 per year. Five hundred and sixty-two report in terms of percentage of which the mean decrease is 35 per cent.

SECTION VII

Approval or disapproval of a plan of insurance for low income groups sponsored by the Massachusetts Medical Society in which the relationship between patient and physician may be maintained? Six hundred and seven approve forty-four approve emphatically. One hundred and eighteen approve with qualifications. One hundred and sixty-nine disapprove nine are emphatic eleven qualify this disapproval. Total disapproval, seventeen per cent ninety-seven (nine per cent) are indefinite undecided or doubtful. Forty-nine (four per cent) do not answer. Seventy per cent approve this principle if a workable plan can be evolved.

COMMENT ON SECTIONS VI AND VII

Any plan of health insurance likely to receive support of the membership must be formulated and controlled by the Society. This phase of the Public Relations Committee's studies is now transferred to the Sub-Committee on Social Legislation and Insurance.

SECTION VIII

GENERAL INFORMATION AS TO SOURCES OF REPLIES

A Type of Community

Urban	551
Suburban	196
Rural	64
Mixed	121
No answer	168

B Type of Practice

General	496
Special	481
Mixed	104
No answer	17
Not in practice	2

Populations and number of doctors practicing generally not computed or referred to directory

SECTION IX

Knowledge of doctors on public welfare lists. Forty three replied "YES," 304, "NO," "Qualified," "YES," nineteen, qualified "NO," eighty-nine. These referred to doctors helped by sources other than welfare living on private incomes, other than professional, receiving medical care in public wards, in debt, etc.

SECTION X—REMARKS

Seven hundred and eighty-two left this space blank. Three hundred and eighteen made a total of 353 comments. One hundred and eighty one expressed various causes of dissatisfaction with conditions of practice. Sixty nine of these specified Massachusetts Medical Society and medical conditions in Massachusetts. Expressing interest in insurance with variable suggestions as to type were sixty, of which two were for outright state medicine. Distrust of the trend to socialism was expressed by twenty eight, two urge employment of legislative counsel to protect the interests of the medical profession. Fifteen comment favorably or disparagingly on the questionnaire.

Although the number of physicians upon whom the depression has borne to the point of actual need is happily small, it is sufficient to justify the adoption of an emergency plan for a welfare committee and the upbuilding by appropriation and (or) assessment of a welfare fund wherewith to relieve the pressing needs of such of our fellowship as have met serious economic adversity. It is recommended that the Society concern itself in relief to such of its members as are now in need.

Respectfully submitted,

HALBERT G STETSON,
PATRICK J SULLIVAN,
ERNEST L HUNT, *Chairman*

APPENDIX NO 13

COMMITTEE ON PUBLIC RELATIONS

REPORT OF SUB-COMMITTEE ON PUBLIC HEALTH AND PRACTITIONER—PUBLIC INFORMATION PRESENTED TO THE COMMITTEE ON PUBLIC RELATIONS ON MAY 22, 1935

The following report has been approved by the Committee on Public Relations and as Chairman of the sub-committee which prepared this report I have been asked to present it to the Council for the Committee on Public Relations.

As a result of its activities since it was formed, the Sub Committee on Public Health and Practitioner, and Public Information of the Committee on Public Relations of the Massachusetts Medical Society has reached certain conclusions on the subject suggested by the title of the committee. The sub committee has several recommendations to make which it herewith presents to the General Committee in the form of motions. It will first deal with the subject Public Health and Practitioner, and then deal with the subject Public Information.

Public Health and Practitioner

In the first place the sub-committee considers that the most intimate relations should exist between the practicing physicians and the officers of the State Department of Public Health and the Local Departments of Health throughout the Commonwealth. The committee feels that the Massachusetts Medical Society should express itself definitely in regard to what it considers reasonable activities of the State Department of Public Health and the Local Health Boards throughout the Commonwealth. To crystallize these thoughts it is moved that the Committee on Public Relations recommend that the Massachusetts Medical Society approve

1 That the prime function of a Health Department is the exercise of the police power of the State for the control of communicable disease and the promotion of sanitation.

2 That all the health agencies throughout the Commonwealth should be an active force in the education of the public in regard to good hygiene and the elimination of preventable disease.

3 That the State Department of Public Health and the Local Health Boards throughout the Commonwealth should eliminate from their activities the treatment of disease, except in so far as is provided by existing mandatory statutes.

4 That the indigent sick in any community in the Commonwealth should be cared for by the individual physician through the proper authorities.

It is realized by the committee that, if these general principles are subscribed to by the medical profession and are approved by the health authorities, it will be necessary to make some definite changes in the programs of Local Health Boards and the Department of Public Health of the Commonwealth.

It is felt that some of these could be put into effect at once. The accomplishment of others of the changes would require considerable thought and change of program. These changes in program include changes both for the various Departments of Health and for the practitioners of medicine. In order to accomplish some of this program it is moved that the Committee on Public Relations recommend that the Massachusetts Medical Society urge

1 That the State Department of Public Health and the Local Health Boards refrain from establishing clinics and doing immunization work for people who are able to pay for this work, except in cases of emergency.

2 That the practitioners of medicine

organize for immunization work and preventive medicine clinics at an appropriate cost to the public and stimulate the public to have this work done and attend these clinics.

3 That the postgraduate courses conducted by the Massachusetts Medical Society include courses which will bring the practitioners up to date on preventive medicine problems.

4 That efforts to eliminate poorly trained individuals from being eligible for admission to examination before the Board of Registration in Medicine be continued by this Society

5 That every effort be made to preserve in Massachusetts only one Board of Registration for license to practice for any group or groups who wish to care for the sick.

6 That the program of educating the legislators in medical problems be kept up and elaborated by the various district societies.

It has been brought out that privately appointed health agencies such as Visiting Nurse Associations are often in need of wise advice in matters of medical policy and in some instances are seeking this advice. Such advice could well be given by the Public Relations Committee of the different district medical societies, and therefore it is moved

That the Committee on Public Relations recommends that the Massachusetts Medical Society urge the District Medical Societies through their Public Relations Committees to furnish on request advisory assistance to local health agencies

Public Information

The committee feels that the Society should have closer affiliation with the associated press and to accomplish this purpose it recommends

That the Massachusetts Medical Society appoint one of its members as a press representative and that efforts be made to have the authorized press agencies as such contact with this representative in regard to any medical matters which the associated press wishes to have appear in the newspapers

CHANNING FROTHINGHAM *Chairman*
MERRILL E. CHAMPTION
WILLIAM G. CURTIS

APPENDIX NO 14

COMMITTEE ON PUBLIC RELATIONS

SUB-COMMITTEE ON SOCIAL LEGISLATION AND INSURANCE

I think it is very gratifying to this Council to know that it has so thoroughly and completely interpreted the wishes of the membership of The Massachusetts Medical Society as evidenced by the report which Dr Hunt made here today. He has made it perfectly clear to you that while probably only a fourth of the membership of the Society answered the questionnaire this

fourth may be taken as a fair cross-section of the whole Society and seventy per cent of those declared in opposition to the principle of compulsory sickness insurance. At your last Council meeting you went on record as declaring that compulsory sickness insurance was not a matter which you could support that it was a matter which you would not only oppose but would actively oppose and you instructed the Public Relations Committee to proceed with the plan of public education picturing the evils of compulsory sickness insurance

The Public Relations Committee, through its Subcommittee on Social Legislation and Insurance, thought that the best way to put over this program would be to encourage the formation and organization of district public relations groups. It felt that this was the first step that must be accomplished before the program could be formally started and I am happy to say that, in the short interval between April 3 and the present day sixteen out of the eighteen districts have been organized and there has been placed in the hands of those sixteen district public relations groups the literature from which their educational programs may be drawn.

It was thought that each district public relations group would be in a much better position than any State group to contact the citizens in that individual district so it was decided the part that the State committee should play would be one of an advisory nature. They should be concerned with organization and they should be concerned with the supplying of literature to the various districts and then say to the districts "Go to it."

The plan was outlined in the resolution that was adopted at the last meeting and that plan seeks to influence public opinion in the matter of compulsory sickness insurance. There was no intent upon the part of this committee and no intent upon the part of the Society to repudiate the principles of sickness insurance. We may find as the result of our survey that is being so adequately conducted by Dr Hunt's committee that some change may be necessary. The Society believes however that it can never countenance any change which places a political or commercial intermediary between the patient and doctor. The Society and the committee feel that it would be a sad commentary on our mentality if we could not find something better than that.

The plan calls for the district committees to appoint from among their numbers, or from among the members of their districts, doctors and particularly doctors of influence to study this literature which we have supplied and will supply to anybody in addition who requests it, so that by the second week in September those districts may be able to send a speaker to a service club to a women's club to a men's club to a parent teachers association,—in fact, to any group with which they may be able to make a contact,—to the end that we may thereby create in the minds of the people a true picture as to the details of compulsory sickness insurance

It is hoped that the men who will receive this literature will study it during the summer so that about the middle of September when everybody is back from vacation, these talks may start simultaneously around the State. The Committee on Public Relations reserves only the right to emphasize certain important things certain important principles which we believe are very important, namely—

(1) That the speaker announce at the opening of his address that he is not speaking as an individual but as a member of The Massachusetts Medical Society and representing The Massachusetts Medical Society

TRAUMATIC CHONDROMALACIA OF THE PATELLA*

Report of Two Cases

BY FRANK A. SLOWICK, M.D.†

The place of chondromalacia of the patella or fissural degeneration of the patellar cartilage as a definite entity among internal derangements of the knee has been satisfactorily established. The work of Budinger¹, König², Lawen³, and Kulowski⁴ places it unquestionably among the obscure lesions of the knee joint. Kulowski, in reporting three cases from Steindler's Clinic, the only ones to be found reported in the English literature, stresses the association of this lesion with chronic arthritis. He feels that small repeated injuries are the etiologic factors.

In some of the cases reported it is not possible to determine whether the condition is a manifestation of chronic arthritis or whether the arthritis follows as the result of trauma and chronic irritation of the joint lining. Key⁵ has recently described two cases of a degenerative lesion of the condyles of the femur, traumatic in nature, which has been followed by an arthritis of the knee joint, the type which is often described as a traumatic arthritis. That this degenerative lesion of the patella may occur as the result of an injury without a previous history of joint disease is demonstrated by the following cases:

CASE 1 E J O M (B C H No 732067), a female aged twenty seven, was first seen at the Boston City Hospital in November, 1933. She complained of pain and disability in the left knee joint. Four months before, she fell on the kitchen floor at home striking her left knee. The joint swelled and she had considerable pain. After a short rest in bed she was able to be up and about. She was treated by strapping with adhesive and physiotherapy. The swelling subsided but the pain persisted. This was present when she was up and about and also when resting. She could not sleep well because of the constant dull pain in the region of the patella and in the front of the joint on both sides of the patellar tendon.

She had no trouble with the knee before her injury, worked steadily as a domestic, and had had no serious illnesses.

The general physical examination was negative, there were no demonstrable foci of infection. She walked with a slight limp on the left side.

Locally, the left knee joint appeared slightly larger than the right. There was a small amount of fluid, and no increase in local temperature as compared with the right side. There was tenderness on lateral compression of the patella and on percussion. Crepitus was present in the infrapatellar region on motion. The motions were slightly limited by voluntary spasm, but the joint could be put through the normal range. There was a complaint of pain in the region of the patella on flexing the knee be-

yond 90 degrees. Aspiration of the joint showed about 5 cc of a yellow, clear and gelatinous fluid. A smear of this fluid showed no cells.

X ray examination showed a mottling of the patella in anteroposterior view, and the lateral view (fig 1) showed an area of diminished density and ir-

FIGURE 1 Case 1. Lateral view of the left knee four months after injury showing an area of diminished density and irregular mottling on the inner surface of the patella in the subchondral region.

regular mottling on the inner surface in the subchondral region.

Subsequent Course At this time it was thought best to continue conservative treatment, and a plaster cylinder was applied to the left lower extremity extending from the groin to the ankle. She was allowed to remain up and about walking in this plaster casing. At the end of a month there appeared to be no diminution of the symptoms, and an operation was advised.

In view of Kulowski's report of cases, a pre-operative diagnosis of chondromalacia of the patella was made, and this was confirmed at operation. Using the medial parapatellar incision, the joint was entered and a small amount of yellow viscid fluid was encountered. The patella was everted and the entire anterior part of the joint was thus exposed. Some congestion of the synovial membrane was found, and the infrapatellar fat pad was hypertrophied. The semilunar cartilages were intact.

The cartilage of the patella was of a bluish gray color, and was covered with a thin film of fibrinoid material, giving the surface a dull appearance in contrast to the white glistening cartilage of the condyles of the femur. The patellar cartilage appeared edematous, and pressure with the handle of a scalpel caused a depression in its surface which would spring out on release of the pressure. In the center was an area of degeneration about one half inch in diameter from which radiated small fissures toward the periphery.

A photograph was taken of the exposed joint, but this proved unsatisfactory. Later a sketch was made which gives a fair idea of the changes as they occurred on the inner surface of the patella (fig 2).

The treatment consisted of an excision of the cartilage, leaving only a very thin layer covering the subjacent bone. The hypertrophied infrapatellar fat pad was also excised, and the joint was closed.

The pathologists' report (B C H No 4246) on the excised cartilage was as follows: "Some degeneration of cartilage, vascularization and ossification in the region of provisional calcification."

*From the Bone and Joint Service of the Boston City Hospital.

†Slowick, Frank A.—Orthopedic Surgeon, St. Luke's Hospital, Pittsfield, Mass. For record and address of author see *This Week's Issue*, page 189.

The patient made an uneventful recovery after the operation, and six months later she was free of pain and had flexion of the knee to an angle of 70 degrees. An x-ray examination at this time showed

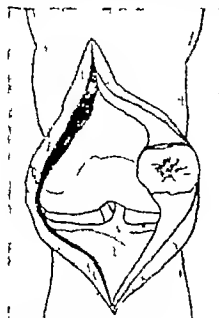

FIGURE 1. Case 1. Sketch of the excised patella at operation showing cartilage degeneration in the center with the res radiating toward the periphery.

that the area of diminished density on the inner surface of the patella had disappeared and the bone was of normal consistency (fig 3).

FIGURE 2. Case 1. Lateral view of the left knee 6 months after operation showing normal consistency of the bone of the patella in the sub-chondral region.

The second case reported here is incomplete, but is of interest from the point of view of diagnosis. After the diagnosis was made and operative treatment advised, the patient refused and did not return to the Clinic.

CASE 2. P. D., a boy aged eighteen was seen in the Fracture Clinic of the Boston City Hospital on September 7, 1934. He complained of pain in the left knee of three weeks duration. Three weeks before he fell striking his left knee. He had no treatment. He was able to be about, but had a constant pain in the knee.

Examination showed some fluid in the joint. There was tenderness in the patella on pressure. There were no signs of an acute infection. A tentative diagnosis of traumatic synovitis was made and an x-ray examination was advised. This film (OPD No. 14500) in the lateral view showed an area of diminished density in the center of the subchondral

area. In this area there was what appeared to be a small sequestrum (fig 4).

In view of these findings a diagnosis of traumatic chondromalacia of the patella was made. Since

FIGURE 4. Case 2. Lateral view of the left knee 3 weeks after injury showing an area of diminished density and erosion in the center of the sub-chondral area of the patella.

treatment was refused the subsequent course in this case is unknown.

Comment. Histologically these cases show principally a fibrillation and degeneration of the cartilage in the central area of the patella. The bone beneath the cartilage is found decalcified and often it is shown to be eroded (Case 2, fig 4). It is interesting to note that it is in this region that the circulation of the patella is poorest. This erosion of the bone in the sub-chondral area occasionally requires enucleation and an arthroplastic toilet as in the first case reported by Kulowski.

The secondary changes which were found in Case 1 in this series consisted of thickening and congestion of the synovial membrane and hypertrophy of the infrapatellar fat pad. Since there were no joint symptoms previous to the injury, it may well be assumed that these changes appear as a result of the trauma.

Summary. Two cases of a patellar lesion which followed definite injuries are here reported. This condition termed variously as chondromalacia of the patella, traumatic chondropathy of the patella and fissural cartilage degeneration has become recognized as a definite entity. The clinical and laboratory findings indicate a lesion which has developed from an interruption of the circulation in the sub-chondral bony structure of the patella.

RECENT ADVANCES IN THE TREATMENT OF RECTAL DISEASES BY INJECTION METHODS IN AMBULATORY PATIENTS*

I The Use of Gabriel's Modified Solution in the Treatment of Fissure-in-Ano

BY NAAMAN STEINBERG, M D †

DISEASES of the rectum are still largely neglected and patients continue to have symptoms for long periods of time before seeking medical advice. This is due in part to a conventional modesty which restrains the patient from submitting to a local examination, and in part to a false impression that the examination is painful and the treatment more so. At least the latter is to be deplored for during the past few years notable advances in the field of proctology have been made and several conditions can now be treated with little or no pain while the patient remains ambulatory. The purpose of the present paper is to present results with the use of Gabriel's modified solution¹ and compare them with those obtained with "Benacol"² (a mixture of equal parts of para amino benzoyl-benzoate and pheno-methylol in 90 parts of rectified sweet almond oil), and Gabriel's original A B A. solution³.

Fissure-in-ano comprises approximately twenty per cent of all anorectal diseases⁴. Owing to its location the lesion causes great pain even when the fissures are minute. For the purpose of treatment it is important to distinguish the so-called true fissures from the false. The latter are the superficial lesions that do not irritate the sphincter muscle and cause spasm. They respond quickly to topical applications of silver nitrate (5 per cent), Ichthyol (10 per cent), or Balsam of Peru (20 per cent) combined with some lubricant such as mineral oil taken orally. True fissures on the other hand have their bases on the sphincter muscle and cause irritation and spasm with resulting pain. Topical applications to the sphincter muscle may cause further irritation with spasm and pain, and therefore are contraindicated. True fissures may be divided into three groups (1) acute, non-indurated with clean, sharply defined edges, (2) chronic or indurated, with thickened borders and often associated with a sentinel pile, and (3) those complicated with infection and showing a seropurulent discharge, induration, and often sinuses or pus pockets that penetrate the mucosa or skin. Lesions of the last type regularly require excision and drainage.

The present study is concerned with fissures of the first and second varieties uncomplicated

by infection. For the past ten years these lesions have been treated with the infiltration of certain medicinal solutions. In 1926, Graham⁵ reported 128 cases treated by injection of a five per cent solution of guinine and urea hydrochloride underneath the lesion. Thirty-eight were acute, ninety were chronic, some of the latter being associated with a sentinel pile and hypertrophied papillae. Immediate relief was obtained in seventy-seven per cent of these cases. The remaining patients required one or two additional injections over a period of one to four months before obtaining significant relief. In 1929 Yeomans, Gorsch and Mathesheimer² reported similar results with the use of "Benacol". In 1929 Gabriel¹ reported his experience with a solution that he called A B A (anesthesin 3 per cent, benzyl-alcohol 5 per cent, ether 10 per cent in sterilized oil). Both solutions gave excellent end results but frequently there was considerable pain during the few hours following the injection. This was often severe enough to necessitate the use of morphine, the pain usually starting approximately one-half hour after injection and persisting in varying degree from one to twelve hours. This was my experience until two years ago when I began to use the modified solution of Gabriel (nupercaine base $\frac{1}{2}$ per cent—benzyl-alcohol 10 per cent—phenol 1 per cent in 5 cc of sterilized oil of sweet almond). Nupercaine (Percaïne) is a well-known anesthetic whose action in watery solution usually lasts from four to six hours. The action of nupercaine base lasts even longer. The phenol is added to intensify the anesthetic power of the latter. The solution in oil, however, is responsible for the more prolonged anesthetic effect, which generally persists for ten days, and in some instances as long as six weeks. As a result of the prolonged local anesthesia thus induced, the sphincter muscle in the injected quadrant is paralyzed and healing can take place more readily. Frankfeldt⁶ reported his experience with the use of this solution and found that the pain and discomfort frequently following the use of other solutions did not occur. My own experience has been the same, and after the use of Gabriel's modified solution, sedatives and analgesics are seldom necessary.

Table I gives the comparative results of treatment with Gabriel's A B A solution (cases 1 to 15), Benacol (cases 16 to 30) and nupercaine solution. It will be noted that after the use of

30	Slight		2 hrs	None	60	None			None

nupercaine not one patient had severe after pain and only in four instances was it necessary to administer mild analgesics. This is in contrast with the occurrence of severe pain in six, and moderate pain in nine patients following the use of Benacol or the A.B.A. solution. After the use of the latter solutions morphine was necessary in seven instances.

TECHNIQUE

My personal preference for posterior fissure in ano is the right Sims position and for an anterior fissure-in ano, the left Sims position. The skin about the anus is cleansed and painted with Scott's solution (mercurochrome 2 parts, distilled water 85 parts, acetone 10 parts alcohol 55 parts). One ampule of Nupercaine, Phenol Benzyl Alcohol in oil which has been slightly warmed to facilitate the flow of oil, is drawn into a 5 cc sterile glass syringe through a large caliber needle. The needle is then changed to one of gauge 20 one and one-half inches long. This needle is introduced into the skin one-half inch from the fissure. With the left lubricated finger inserted into the anal canal to guide it and prevent perforation of the mucosa, one cc is then injected under the bed of the fissure, care being taken, if induration is present, not to inject the indurated tissue. The needle is now withdrawn approximately half way, and 1½ cc. is injected into the sphincter muscle and adjacent tissue on either side of the fissure. The remaining solution is finally in-

jected well behind the lesion, care being taken that the solution used should not be injected intradermally or too superficially beneath the mucosa, as sloughing may result. The tissues are then gently massaged for about one minute with the left index finger in the anal canal, and the right finger on the perianal skin. The sphincter in the injected quadrant relaxes almost immediately and the fissure becomes plainly visible. If a sentinel pile is present it is removed with a pair of scissors after the injection. Supplementary anesthesia is unnecessary. Topical applications may now be used to facilitate healing. Pure ichthyol or silver nitrate solution (10 per cent) may be applied to the fissure without pain or discomfort.

When the patient is examined the day after the infiltration the sphincter is found to be relaxed and the finger can be introduced into the anal canal without pain or discomfort. The patient's only complaint is numbness in the injected area. Rarely there is an inability to control flatus. Complete healing usually takes place seven to twenty-one days after initial treatment. It is unnecessary to make any changes in the diet. Mineral oil is regularly prescribed to facilitate easy movements.

Serious complications have not been observed after this treatment.^{1, 2, 4, 6, 7} In the present series there were four chemical abscesses, two of which resulted in small fistulae. The abscesses healed spontaneously and the fistulae were excised under Nupercaine (1 to 1000). There

were also two instances of superficial sloughing which healed spontaneously. When sloughing occurred it caused slight discomfort for several days, and healing took place within one to three weeks.

CONCLUSION

The comparative merits of the Nupercaine Phenol solution in the treatment of fissure-in-ano was studied in thirty patients. Little or no discomfort followed the use of this solution in contrast to the occurrence of severe pain after the use of Benacol or Gabriel's original solution. Significant complications did not oc-

cur. Fissure-in-ano, uncomplicated by infection, can be treated successfully in ambulatory patients without inconvenience or loss of time.

THE ETIOLOGY OF CONGENITAL AND HEREDITARY DEFORMITIES*

BY SETH M. FITCHET, M.D.†

WE, as surgeons, are not greatly interested in the problems and researches of the geneticists. Yet very possibly it is in this field that the solution of the problem of congenital and hereditary malformations lies. Perhaps it is not the surgeon's function to know or care about the etiological factors in malformations for it may be that his chief function is that of a mechanic striving to correct the deformities as they are presented to him.

Perhaps it is safe to say that the explanation of congenital deformities lies in the field of genetics but that the treatment of them lies in the field of surgery, and that the prevention of congenital deformities may become a joint problem of the geneticist and the surgeon, with the help of the physiologist and the biochemist.

Explanations or attempts at explanation of congenital and hereditary anomalies are many and varied ranging from the superstitious and fantastic to the pseudoscientific for the range and variety proclaim our almost complete ignorance of the problem.

In this paper an attempt is made to point out some facts which may add to our concept of the etiological factors in congenital deformities.

We know that the individual develops from an ovum. We know that normally the ovum is activated by fertilization by union with the sperm. We know that experimentally an egg can be made to develop and produce its kind without the aid of the sperm that shaking mechanically, pricking with a needle temporary sudden change of temperature, hyper- and hypotonic solutions any change of surface tension chemical stimulation by the salts and acids may provoke cleavage and development.

We know, for instance, that if we treat the sperm of the Triton (Salamander) by exposing

it to the B and Y rays and then inseminate the ovum of the Triton that that ovum will cleave and develop but the development will be substandard and malformations will be present.

Every ovum and every sperm has its own allotment of particles in its nucleus. The diploid chromosome number is 24 in the fertilized Triton ovum. The diploid chromosome number is 12 in the ovum inseminated with the radiated sperm. Cleavage takes place and development goes on but there is a definite lack in the inseminated egg as compared with the fertilized ovum.

Gregor Mendel (1822-1884) offered proof three generations ago that genetic units determine the inheritance of characteristics.

Otto Butschli, professor of zoology at the University of Heidelberg in his studies of the constitution of protoplasm and the structure of the nucleus and methods of cell division demonstrated the existence of these genetic units, the chromosomes.

Thomas Hunt Morgan went one step farther and gave us the concept of the gene as the genetic unit.

August Weismann (1834-1914) professor of zoology at Freiberg University following the publication of "The Origin of Species" accepted the evolution theory and forcefully defended its thesis and became the leader of the Neo-Darwinian school. Weismann materially emphasized the present theory that heredity has a physical basis. He modernized the old preformation theory, for he believed that every peculiarity of the adult organism was represented by a special carrier of heredity, a determinant which is present in the germ-plasm. This primordial rudiment was not the organ or part itself, but that there was for every organ and for each of its special parts a definite particle of protoplasm which represented the particular structure or part of an organ. The

earlier chromosomal theory regarded the individual chromosomes as being aggregates, more or less closely bound, of a large number of corpuscular genes. Weismann's theory is that the gene, joined in groups called *ids* corresponds directly to each character and each differentiation of the complete individual and that this gene exists as a discrete particle of substance in a particular chromosome of the germ cell nucleus.

Weismann's theories have been criticized as superscientific speculations and assumptions yet, in 1933 Professor T. S. Painter of the University of Texas, working with giant chromosomes found in the salivary gland cells of the fruit-fly larvae (seventy times the size of ordinary chromosomes), demonstrated on them numerous cross bandings, which always had the same sizes and spacing on comparable chromosomes. Painter also found that with particular groups of these bands groups of known genes could be related.

In September, 1934 Calvin B. Bridges announced a further step based on the brilliant work of Painter.

Dr. Bridges went to work with Professor Painter's results before him and demonstrated that the chromatin was not the important part of the chromosome, but was the matrix or outside wrapping of it. He demonstrated that the bandings observed by Painter were in reality the edges of solid disks that ran clear through the chromosome, strung together much like beads of Indian wampum. He also saw that each *gene locus* corresponded with some special size or shape of bead, always in the same relative position and always the same in all chromosomes examined.

Each disk proved to be subdivisible also not unlike thin slices from a large telephone cable, each wire of the cable in cross section visible as a minute dot on the face of the disk. Like the cable, before slicing there is a continuity from disk to disk, between these rods or wires. So small are these subunits that many of them are hardly larger than single molecules of one of the more complex proteins. They may, indeed, be single molecules, or they may be small groups of molecules acting together.

Whether these tiny units are genes themselves, or only the genophores or gene bearers is not of course known, but it is interesting to see how these very recent findings fit in with the much criticized Weismannian theory that the "gene exists as a discrete particle of substance in a particular chromosome of the nucleus of the germ cell."

Now, if the nucleus of the sperm of the Triton can be modified and destroyed by exposure to B and Y rays so that the ovum inseminated with this sperm produces a deformed adult Triton is it not possible or even probable that the explanation of the multiplicity of deformities encountered may be found in some chemical mechani-

cal, thermal or nutritional alternation or damage to the gene or disk, or disk content of the chromosome? And if therein lies an explanation for the congenital deformities we may truly expect to find therein the explanation, based on Mendel's formula of the hereditary deformities.

Hugo de Vries in experimental work with plants has demonstrated that abnormal characteristics appear spontaneously and are transmitted to offspring, and eventually disappear by cross-breeding—the mutation theory as an explanation of the etiology of congenital and hereditary deformities. It will be noted that the mutation theory is not at variance with the Weismannian theory and the observations of Painter and Bridges.

Murk Jansen (Leiden, Holland) has given considerable thought to the problem and has an intriguing explanation for many of the skeletal deformities, an explanation, however, which cannot be accepted. He states that we must look for mechanical malformations due to pressure which has acted upon the fetus; that variations in the size of the amnion and differences in hydrostatic pressure interfere through pressure or through nutrition with fetal life and development—a quantitative alteration of normal growth.

In November 1934 Professor H. J. Muller of the University of Texas, and Dr. A. A. Prokofyeva of the Soviet Academy of Sciences Institute of Genetics, working together with bits of chromosome material having a diameter of sixteen millionths of an inch, have demonstrated that somewhere on this wee bit of stuff there was room for several genes.

By bombarding bits of chromosome material, they could produce "translocations" of particles, i.e. a dislodgment of bits of chromosomes carrying a few genes which would find their way to an entirely new place in the arrangement within the chromosome. These translocated bits of chromosomes, carrying genes with them, would interact with the genes already in place and produce mutations in the resulting organism. This suggests that the position of the gene or gene group its interaction with its neighbors its "position effect" may be of real importance.

The work of Professor Muller also indicates that it is possible for genes to be entirely divorced from the chromosome without killing the individual but the gene-deficient individual will show abnormalities.

In December, 1934, Dr. C. W. Metz and Miss E. H. Gay members of the research staff of the Carnegie Institution of Washington working in the laboratories of Johns Hopkins University, using slightly different methods, found a net-like or honeycombed structure within or between the band-like disks of which Painter, Bridges, and others have recently shown the chromosomes to consist.

These disk-like structures have been likened to "temples of destiny" on the "streets" of heredity which are the chromosomes. If this analogy is carried farther, "the inter-disk cavities found by Dr Metz and Miss Gay might be called the rooms within the temples. But, as yet, nobody has actually seen the powerful, controlling goddesses who dwell in these rooms the modern Fates, otherwise the Genes."

In the light of the above, the work of Halsey J. Boggs becomes most interesting and suggestive. Boggs exposed mice to x-ray and eventually produced a race of club-footed mice. Perhaps we might reason that following the bombardment with x-ray, as in the case of Professor Muller's experiments, there was a translocation of chromosome particles carrying genes, and that the interaction of the translocated genes with their neighbors produced the anomaly of club feet and that in breeding carried this anomaly through hundreds of mice.

The club foot lent itself well to observation as would any other external deformity. The race of mice developed had deformities of viscera which did not lend themselves so well to study and observation.

Boggs observed through the transparent, pregnant uterine wall that there was an apparent arrest of embryonic development associated with an observed stripping up of cutaneous epithelium by clear, lymph-like fluid arising from perivascular lymph channels. Into this bleb-like structure he observed an extravasation of

blood, and, later, a firm hematoma. This hematoma became absorbed prior to birth. The extent and location of the bleb-hematoma on the extremity determined the degree of deformity—club foot, hypodactylism, syndactylism, or "congenital amputation", etc.

In order to be certain that the observed intra-uterine anomalies were the same as those that were later seen in the litters, it was found that the intrauterine embryo could be marked by pulling its tail through the thin, transparent uterine wall, nipping off the tail, and thus when born the mouse could be indisputably identified.

From these suggestive and instructive data and observations, it is fair, I think, to state that definite advance has been made in the search for the etiological factors involved in congenital-hereditary deformities. Should this factor prove to be a damaged or translocated gene of a complex chromosome, we might confidently expect to find the damaging or translocating agent—perhaps infection, metabolic deficiency, mechanical injury, thermal or chemical factors, or some as yet unthought of substance. The intensive work now going on in the genetic laboratories of the world should be watched with keen interest by the surgeon interested in congenital-hereditary deformities, for soon they may determine for us the long-sought-for etiological factors. With this information at hand, the prevention of congenital hereditary deformities need no longer be the chimerical dream that it now seems to be.

THE 'PHTHALEIN TEST OF KIDNEY FUNCTION IN ANEMIA*

BY EARLE M. CHAPMAN, M.D.†

AN occasional criticism of the phenolsulphonephthalein test of kidney function has been that the excretion of the dye may be decreased in the presence of anemia.¹ Christian² found that the output of dye was decreased in six of fourteen patients with severe pernicious anemia, however in three of these there was a very slight albuminuria. One may assume that a diminished blood volume decreases the carrying capacity for the dye, however Marshall³ has already pointed out that 'phthalein in the blood is contained only in the plasma and not in the red corpuscles. Therefore one would not expect a diminution in the number of red cells alone to alter dye excretion.

The constancy of the volume of blood plasma has proved to be a surprising feature of anemia. In pernicious anemia Bock⁴ has shown that the plasma volume is usually normal while in chronic secondary anemias Keith⁵ has found

the plasma volume normal or increased. In blood loss due to hemorrhage there is an immediate diminution in plasma volume but, in the absence of shock, this is speedily adjusted to normal if the fluid reserves are adequate. Even in nephritis⁶ with or without edema the plasma volumes are normal. Thus the constancy of the volume of blood plasma in anemia maintains the carrying capacity for phenolsulphonephthalein and in view of this we would not expect a significant change in the dye excretion.

To investigate the validity of such a criticism from the practical standpoint we have studied eleven cases of severe anemia who showed no signs of cardiovascular or renal disease. The urine in each case was normal. A fractional 'phthalein test of kidney function was done on each patient, the technique has been described in a previous communication⁷ and consists briefly in the following. The patient emptied the bladder, drank 400 cc of water and one half hour later 10 cc of phenolsulphonephthalein was injected intravenously. Specimens of urine

*Massachusetts General Hospital Boston.

†Chapman, Earle M.—Assistant in Medicine, Harvard University Medical School. For record and address of author see "This Week's Issue" page 189.

were then obtained fifteen, thirty, sixty and one hundred and twenty minutes after the injection. The first two collections are the most important as they show the high initial output of dye which is the significant feature of 'phthalein excretion'.

JACOB ZAHALON, AND HIS BOOK, "THE TREASURE OF LIFE"

BY HARRY A. SAVITZ, M.D.†

BY 1630, when Jacob Zahalon was born in Rome, six years before Harvard College was founded, the Jews already had a long tradition of medical scientific literature. Not to mention medical references in the Bible and the Talmud, scientific medical literature begins with the Tenth Century with Isaac Judaeon (832-930) in Egypt, and with Shabbethai Donnolo (915-982) in Italy.

Jewish medical men were primarily dominant in Arabic speaking countries in the East. Then we find them in Europe in Mohammedan Spain, and later in the same country when it came under Christian rulers. But what is primarily of interest to us is Italy. In Italy from Donnolo to Zahalon there was a continuous uninterrupted tradition of Hebrew scientific medical literature for seven centuries.

The Jewish physicians were not only medical practitioners, but also authors. They wrote original works as well as translations from other languages. For example, to mention only a few,

Isaac Judaeon's famous treatise on fever, Donnolo's work on Materia Medica, Maimonides' numerous works, Nathan ha Meati, who translated the Canon of Avicenna (1279) and Hillel ben Samuel of Verona (1220-1295) who translated Bruno's work on Surgery.

These Jewish medical men not only practiced among their own people but among Christians and Mohammedans as well. Their services were often engaged by Kings, Princes, and Popes, as, for instance, Isaac physician to Pope Boniface VII, Manuele and Angelus, Manuele, physician to Boniface IX, Jacob of Capua, court physician to Charles II, and Isaac, Court Physician to King Robert of Anjou.

These Jewish physicians were also connected with institutions of learning. In Salerno, the leading medical school in the Occident, as early as 848, Joseph taught there and in 855 Joshua, both Jewish physicians. In the eleventh century lectures are said to have been delivered there in Greek, Arabic, Hebrew and Latin. The same was true of the medical school at Montpellier, where Jacob ha Katon was dean of the medical faculty and Jacob ben Machu ibn Tibbon,

Read before the Boston Medical History Club.

†Savit, Harry A.—Asistant in Medicine, Beth Israel Hospital. For record and address of author see "This Week's Issue," page 166.

called Profatius Judaeus, dean of the medical faculty about 1306

Like most Jewish scholars of the Middle Ages, a great many of these Jewish physicians were also Rabbis

Jacob ben Isaac Zahalon was born in 1630. He was a descendant of the noble Zahalon family of Spanish origin, whose members after exile from Spain settled in Italy and in the Orient and distinguished themselves as rabbis and scholars. Jacob received the traditional education in Hebrew literature. He also acquired a medical education at the University of Rome, where he received his degree of Doctor of Medicine. Acquiring early a high reputation both as physician and Talmudist, he was called to the rabbinate of Ferrara, where he served both as Rabbi and physician until his death in 1693.

Zahalon was a prolific writer. He wrote a book called, "Ma'alahyot Tobot", an abridgment of the "Hobot ha-Lebabot" of Bahys ben Joseph ibn Pakuda. This is divided into thirty chapters corresponding to the number of days of the month, each chapter being followed by prayers for various occasions. In its preface, Jacob enumerates several works he left in manuscript, on Maimonides, commentaries on some books of the Bible, on theology and philosophy. His medical work, the "Ozar ha-Hayim" was published in Venice in 1683. This book is Part III of a work called "Ozar ha-Hochmath". It is divided into thirteen parts, the last of which on mental disease, remained unpublished for lack of funds.

The age of Zahalon was not a period of numerous medical specialties. Therefore, his book is encyclopedic in character, beginning as it does with general hygiene and ending with mental diseases, it covers practically every branch of medicine. The thirteen divisions of the book are as follows:

- 1 On General Hygiene
- 2 On Fevers and their Cures
- 3 On the Pulse, Urine, and the Tongue
- 4 On Poisons and their Antidotes
- 5 On Signs and Causes of Disease
- 6 On Remedies Simple and Compounded
- 7 On Disease of the Head, and Treatment
- 8 On Disease of the Chest, its Treatment and Cure
- 9 On Abdominal Disease and Treatment
- 10 External Diseases, Surgery
- 11 Women's Diseases and Treatment.
- 12 Children's Diseases and Treatment.
- 13 Lecture on Mental Diseases which are like Physical Diseases (This part not published)

In his introduction he discusses the Rabbinic attitude toward medicine, quoting the Bible, Talmud and Maimonides. He outlines the contents of his book and says, "At the end of each chapter, I shall illustrate by a successful case of mine or some other physician, in order to encourage patients." Zahalon was devoted to med-

icine and had the patient's concerns close to his heart. He stressed the ethical side of medicine. He next enumerates the admirable aphorisms of medical conduct, 77 in number, which had been published by the learned physician, Abraham Zacuto Lusitano (1576-1642, great grandson of Zacuto, the historian and astronomer), of blessed memory, in his voluminous work, "De Medicorum Principium Historia". Translated from the Hebrew, they are as follows:

- 1 A physician shall be God fearing
- 2 He shall be well dressed
- 3 He shall not indulge in unprofitable chatter
- 4 A physician shall not be miserly and niggardly
- 5 He shall not be primarily interested in fees
- 6 He shall not be envious
- 7 He shall not be haughty and snobbish
- 8 He shall not be stubborn in his judgment of the opinions of others superior to him in knowledge
- 9 He shall admit his mistakes if he has erred
- 10 He shall accept joyfully and gracefully rebuke from one greater than himself
- 11 He shall be even tempered
- 12 He shall be by nature wise and intelligent
- 13 The physician shall constantly be guided by intelligence
- 14 He shall possess few and good medical reference books
- 15 He shall make use of books by expert scholars
- 16 He shall not take upon himself to cure those who are beyond his skill
- 17 He shall refrain from testifying and promising anything that is not the truth
- 18 He shall endeavor to treat minor illnesses as if they were major ones
- 19 He shall not minimize a severe illness
- 20 He shall cultivate the habit of discussing and consulting about his patients with other physicians
- 21 He shall limit his practice so as to devote sufficient time to his patients so that he may not err
- 22 He shall not burden himself with technical terminology of the different diseases, but shall know the nature of these diseases and their cures
- 23 A physician shall not ignore the slightest fact for it may prove a beneficent sign in the diagnosis
- 24 He shall not delay too long the treatment of the patient.
- 25 He shall not do anything unless he has a good reason for it
- 26 He shall be careful not to make promises
- 27 (Text obscure)
- 28 He shall do everything according to the art of medicine
- 29 He shall make use of both experience and theory
- 30 He shall be diligent and speedy in his acts without any indolence in time of necessity
- 31 A physician shall have regard for the value of human life
- 32 His main purpose shall be the healing of the patient
- 33 He shall take into consideration the difficulty and the danger involved in each treatment
- 34 He shall take a firm stand against popular prejudices

- 35 At times it is necessary to cheer up the patient with soft, kind words
- 36 He shall try to cure the patient with speed and with confidence.
- 37 He shall not regret rational practice even if it should not be in accordance with standard treatment
- 38 He shall observe carefully the matter of secretions
- 39 Whatever he does shall depend on the rules of medicine and he shall study carefully what nature does with regard to the particular illness
- 40 If nature does not act then let the physician use medication.
- 41 But if nature acts properly then let him not interfere
- 42 If it is the cause of nature to act in a definite time let the physician not interfere
- 43 Let him be careful to give medication in the proper day and hour
- 44 He shall be careful in giving strong expectorants if not urgent merely because the milder ones did not act.
- 45 Before prescribing an expectorant he shall treat the secretions that the patient may find it easy to expel them
- 46 In dispensing medication let him start with milder ones
- 47 The physician shall choose the proper time for prescribing laxatives for example in April and September but if necessary even on holidays but a mild one
- 48 The physician shall take into account various astrological signs as to which days are good or bad for prescribing laxatives
- 49 In case of venesection he shall take into consideration the condition and temperament of the patient.
- 50 He shall take cognizance of the patient's temperament in determining whether he can bear a strong purgative
- 51 He shall also take into consideration the patient's habits
- 52 He shall determine the condition of the secretions which need to be expelled
- 53 He shall pay attention to the movements of the secretions
- 54 Let him determine at which point he wishes to withdraw the secretions whether from above or below whether by sweating etc.
- 55 Let him not treat every patient with medication for sometimes mere diet will do if the illness be mild and the patient weak
- 56 A body given to extremes of temperament shall be treated with medications correspondingly opposite of nature a body not given to extremes should be treated with medications of a correspondingly similar nature
- 57 An abnormal excretion shall not be directed through a channel in the head or through any weakened or diseased channel.
- 58 A prolonged illness may often be cured by change of place and environment
- 59 Let him always help nature for that is the primary factor in health
- 60 Let him observe the strength of the patient and particularly his mental condition
- 61 Let him ascertain the seat of the injury
- 62 Let him ascertain the primary cause and which are the sequelae
- 63 If he cannot diagnose the case let him be satisfied by merely prescribing a diet.
- 64 Let him observe what is useful and what is harmful
- 65 Let him observe the effect of change of place and climate for treatment will change accordingly
- 66 It is of prime importance to observe what is the most endangering factor and focus his treatment toward that.
- 67 He should not prescribe a powerful expectorant in the early stages of the ailment before the secretions are softened
- 68 The physician shall keep his wits when he observes complications during the state of illness for then is his responsibility the greatest
- 69 The physician shall alleviate first pain before the other symptoms for pain weakens the strength a great deal
- 70 He shall correct first either coma or insomnia.
- 71 Before prescribing any expectorant the physician shall first of all purge the patient's bowels
72. In prescribing the physician shall keep in mind the difference in temperament, the hot and strong of a man and the weak and cold in a woman and prescribe accordingly
- 73 He shall be careful in prescribing to the very young and the old for they are weak
- 74 He shall be cautious in prescribing to infants
- 75 The physician should be familiar with anatomy
- 76 A physician should also be acquainted with surgery
- 77 He shall study the properties and composition of drugs

Then Zehalon adds some general advice of his own to the physician

"It is advisable that the physician before beginning his practice should for a long time accompany a skilled physician in his visits to the sick. What he hears his teacher say concerning the treatment he should make note of as soon as he comes home and he should also study carefully the medical books on the subject of the disease. If he is in doubt about anything he should inquire from other physicians or from other books in order to clear up the points in doubt. Even if the disease is serious, the physician should speak encouraging words to the patient. If he is told about a cure on the authority of another physician, he should not scorn it. If another physician is with him (in the case) he should not disregard his opinions if they are good and if they are not he should not state it openly to others, but privately to his colleague. When the patient is cured, the physician should not prolong his visits when there is no necessity.

He should give direction how the patient should conduct himself so that the disease should not return and that he give praises to the Holy One, blessed be He, the merciful physician who cured him. The physician should not sell the drugs himself, but the patient should send to the druggist. And before he prescribes he should seek God to instruct him what is proper for a sick man. Should he find that the patient is dangerously ill he should inform his relatives, so that if he dies, they do not

slander him, but also that they make every effort to cure and that they do not raise objections to the expense. When the physician visits women he should be modest, and should not follow the evil thoughts of his heart. And he should not accept a fee from the poor nor from relatives and close friends, and should not accept a fee for his services on holidays and Sabbaths. Others permit this to be done by including it in the general charge for the week days. If he sees that a friend desires to remunerate him daily in order not to be obliged to give him an expensive present at the end or in order that he may be at liberty to call him again, he may take a fee. Although the physician who visits the sick is performing a religious duty and it is not fitting that he receive pay for this, nevertheless, the Rabbis permitted it as remuneration for the time spent just as they permitted teachers who teach the Torah to receive pay in order that they may be able to live by their profession."

In conclusion Zahalon urges that "the physician should recite at least once a week the 'Physicians' Prayer', which he composed and published in the 'Sepher Margaliyyot Tobot'", printed in Venice in 1665

THE PHYSICIANS' PRAYER

"Lord of the Universe! Thou, alone has made the Heavens and the Heavens of Heavens and all their hosts, the earth and all that is upon it, the seas and all that is within them. Thou givest life to all and sustenance to all. The hosts of Heaven bow to Thee and there is neither among those on high nor among those underneath anyone who would tell Thee what to do. Thou has formed man from the dust of the ground. Thou has breathed the spirit of life within his nostrils. Thou hast caused him to rule over the words of Thy hand. Everything Thou has placed under his feet. For his sake thou has created all. If he meritoriously performs the will of his Master, his hand ruleth over all things, if not, the hand of all is upon him.

"Thou dost punish him with afflictions and ailments. He is chastened also with pain on his bed and all his bones grow stiff. His flesh is consumed away that it cannot be seen and his bones corrode to unsightliness. His soul draweth near unto the pit and his life to the destroyers (Job 19, 21, 22, 33). But if he repents completely before Thee, Thou art pleased with him and Thou wilt cure him as it is written 'He sent His word and healed them and delivered them from their graves' (Ps 107 20). For Thou art the merciful and faithful healer, as it is written 'I have wounded and I heal' (Deut 32 39), in order to make known to all the denizens of the world that Thou art the healer

and unto Thee is the power and the glory. From Thy established habitation Thou lookest down upon all the inhabitants of the earth. For their special benefit, hast Thou created in Thy world many drugs by which to cure the sons of man and in Thy wisdom Thou has commanded them to cure one another by means of these medicines, as it is written 'He shall cause him to be thoroughly healed' (Ex 21 19).

"Since, therefore, Thou hast favored me with kindness and has crowned me with honor and glory and Thou hast made me worthy of knowing a bit of the science of medicine, therefore I wish to perform Thy desire, O Lord. I am minded to busy myself with the practice of medicine in Thy Holy Name and through Thy assistance, 'that Thou mayest be justified when Thou speakest and be in right when Thou judgest' (Ps 51 6), for Thou art the physician, not I. I am but as the clay in the potter's hand, in the hand of the creator of all things and as the instrument through which Thou curest Thy creatures. I do not rely upon my wisdom, nor do I place my trust in the drugs and herbs and medicaments which Thou hast created, for they are but the means to fulfill Thy will and to proclaim Thy greatness and Thy providence. Since the practice of medicine is fraught with perils, and as I am a man of folly and of no understanding, fearing lest I grope at noonday as the blind grope in the dark, therefore do I cling to the fringes of Thy kindness and do follow Thee, in the light of Thy countenance will I walk and in Thy light will I behold light, 'for Thou dost light my lamp, Lord my God doth lighten my darkness' (Ps 18 29). Therefore, may it be Thy will, O Lord my God and God of my fathers, to endow me with good understanding and to bestow upon me knowledge and insight and to cause the eyes of my understanding to shine so that I may discern and diagnose the ailment of the body thoroughly and correctly in all the cases that come to me, instruct me as to the drugs suitable to each one in accordance with his needs and in accordance with proper time when they are fit, so that I may not err in my acts or in my words, 'lest my enemies see and rejoice' (Prov 24 17). Support me that I do not stumble and that no mishap occurs through my hand. Recompense me with Thy many kindnesses for to do kindnesses have I entered into the profession of medicine, to save the lives of Thy people Israel. Assist me and protect me from insult and shame.

If there come to me any patient whose allotted time is about to end and whose affliction is heavy, may it be Thy will that I cause not the hastening of his death (God forbid) even by one second. Teach me to administer drugs so as to retain his soul with him until his fated hour arrives. And if he die may it be Thy will that his friends, his companions and the mem-

bers of his family do not accuse me and that they do not suspect me of being the cause of his death, but that they accept it as the just decree of God, of the King in Whose hand is the life of all living and the spirit of all flesh. But if his appointed time has not arrived and Thou art casting him down with pain because of Thy mercy in order that he repent completely before Thee for Thou hast 'no pleasure in the death of the wicked, but that the wicked turn from his way and Live' (Ex 33 11), may it then be Thy will that Thou causest this merit to fall to my lot and that Thou instructest me what I shall say in order to bring him to repentance and to accept his affliction with love for Thee so that it may be an atonement for all his transgressions, and that through me Thou sendest forth Thy command and cure and that thereby I shall be beloved on high and honored below.

"Save me from hate and strife. Let me not be envious of others, and may others not envy me. Establish between me and other physicians love, brotherhood, peace and good fellowship. Let me not be put to shame nor disgrace before them, but let me be respected by them. Make me wiser than my enemies. May my wisdom and the knowledge which my lips utter clearly so that there are none to utter an evil word against me or my deeds, and if perchance such evil word be spoken let no one give it credence. Let not my colleagues err and permit me to rejoice. If, however, they do evil in their work, may it be Thy will to place a muzzle to my month and let me not reveal their wrongdoing, but may I have the merit to repair what they have injured. Let me find grace and favor and kindness in Thy eyes and in the eyes of all who see me and hear me so that they do what I order for a patient if the treatment is proper, but if the treatment is not proper then harden their hearts that do not do it, but let them not make it widely known lest (God forbid) I be disgraced. O Lord, God of the spirit of all flesh!

'I ask one favor of Thee, that Thou give strength to my memory so that when I go to visit a patient, Thou make known to me at once which cure will benefit him whether I have studied it or not, I supplicate Thee, Cause of all Causes, that Thou cause the chain of circumstances to act in such manner that Thou bringest into my hands the medical book in which I may study his treatment or that I may listen to an argument between physicians that will teach me to know his cure. For Thou art the one who brings about the succession of causes in Thy Universe, as it is written 'And they are turned around about His guidance, that they may do whatsoever He commandeth them upon the face of the habitable world' (Joh 37 12.) I pray Thee, O Lord, that Thou bring upon me merit in this world and not demerit. (May God

forbid!) Do not cause that any evil thing be found in my hand. Let no corruption come from me, so that I should cause any man's death nor even the loss of his limbs, neither willingly with intent nor unwillingly without intent, let me not be included in the category of the 'best physicians are fit for Gehenna' (Mishna Kiddushin IV 14.) 'Gather not my soul with sinners, nor my life with men of blood' (Ps 26 9)

"But for the merit which Thou mayest bring to me in that I may preserve lives of Israel, Thy people, whom Thou wilt save from death through me, grant that I may deserve to walk about this world in the pleasure of beholding the good of Thy chosen ones, rejoicing in the joy of Thy people of glorying in Thy inheritance. May my eyes see Jerusalem, the peaceful habitation. May I walk before the Lord in the land of the living. Let not Satan attach himself to the work of my hand, for to purify and to cleanse have I come!

"My God, deliver me from the hand of the wicked, from the palm of the perverter and oppressor and place me not in his hand even for one moment lest he entice me to practice wantonness (God forbid!) to administer a poison or drug to injure some man or some pregnant woman (God forbid!) If he try to entice me, meet him, humiliate him, deliver my soul from him. 'O Lord, I am oppressed, be Thou my surety' (Isaiah 38 14) for Thou art my hope, O Lord God, my trust since my youth. Cleanse my mind and purify my thoughts that I think no evil about any woman, whether virgin or wife, when I visit her that do not go about my own heart and my own eyes.' (Num 15 39) Save me from all injury, disease and infirmity. 'May the sun not smite me by day nor the moon by night' (Ps 121 6)

"I pray, O Thou Master of kindness and mercy, open my eyes that I may discover the secrets of Thy wonderful deeds and that I may know the peculiar curative powers which Thou has placed in herbs and minerals, in seeds and flowers, in roots and leaves, in wood and fruit, in wines and oils, in waters and in other liquids, in living organisms which are in the heavens above and in the waters under the earth, in simple and composite structures and that through them I shall tell of Thy might to all generations to whom Thy greatness shall come. May it be Thy will to give Thy blessing to all the works of my hand and to recompense which is given me against my will so that I may look upon it as an omen of good and that I may apply it to good and righteous purposes before Thee, and to magnify and glorify Thy law. And may my sustenance and that of my children and children's children come from Thy hands and not from the hands of men of flesh and blood and may it be in abundance so that

I be not forced to take anything from the poor and sick but, on the contrary, that I may be able to give unto them what Thou hast bestowed upon me, for from Thee come all things and from Thy hands I return to Thee Endow me well that I succeed and prosper in all that I do, and especially in the work of healing do Thou magnify Thy kindness so that patients call me to whom cure is possible and who may be cured completely through me And let those not call me who are incurable and whose illness is fatal because Thou hast decreed that they may not be cured 'Let my soul not come unto their council, unto their assembly let my glory not be united' (Gen 49 6) If people consult me because of my knowledge let not the foot of pride overtake me, but let my soul be 'like a weaned child with his mother' (Ps 131 2) May no evil desire nor vile eye have power over me Let me not be brought into temptation or shame Save me from the reflection of sin, and transgression and iniquity now and forever, and clothe my soul with glorious raiment, the crown of glory of good morals as is becoming to one who finds grace in Thy eyes Lend strength to all my senses so that they may tell the truth in everything which is brought before them that I may not be mistaken in any one of them neither in taste, smell, sight, hearing nor touch, let them tell me concerning what is positive that it is positive, what is negative, negative, what is bitter, bitter, what is sweet, sweet, so that no injury result to any of my patients because of the weakness of my perceptions Strengthen likewise the power of speech of the patient and the vigor of his understanding and his memory so that he tell me the truth as to the causes of his ailment and no falsehood in regard to them lest I also, be led into error and thus fail to understand the causes of his disease from his words and from the symptoms of his disease, let me be fit and learn to prognosticate correctly to the patient in order that my words and warnings may be verified and my injunctions observed 'Uphold me according unto Thy word that I may live, and put me not to shame in my hope' (Ps 119 116) Do not destroy hope from out my heart, do not incline me to do evil, do not hide Thyself from my supplications, be gracious unto me and answer me, hearken unto my prayer Indeed Thou hearkenest unto my prayer and I must give thanks for everything and sing Hallelujahs and praise Thy name, for goodness is in store for Thy saints! May I increase in greatness and mayest Thou comfort me! May these words which I have supplicated to the Lord come to pass, etc."

This prayer is a psychoanalytic characterization of the man, Zahalon He looked upon medicine as a sacred calling The physician is

merely God's servant on earth to help his fellow-men He reveals the famous adage—that the physician merely treats and God cures—as he says, "Thou art the physician, not I" He fully realized the great responsibility that medicine places upon the physician and he is also aware that to err is human So he prays fervently for divine guidance so that he may increase his knowledge and not err But book knowledge alone is not sufficient to make the great physician To this must be added the physician's own intellect and faculties of observation So he prays for the preservation of his health and all his faculties, so that he may serve mankind best He has not chosen his profession for the sake of wealth or glory But he prays for sustenance so that he may not be forced to accept anything from the poor for his services, but rather share with them For what nobler ideals can one ask?

We hear a great deal at the present time about personal interviews and personal aptitudes of students who wish to be matriculated in medical schools, for it is claimed that personality is a factor in the making of a good physician It is interesting to note that Zahalon in the Seventeenth Century, advocates this principle He quotes the author of Olath Shabbath¹, who says, "A physician must possess these requirements in order to secure the patient's confidence (1) He must be a respected man of good appearance, who will find favor in the eyes of all the people, the patient will trust him if he is a God-fearing man and a man of good stock" But personal appearance is not sufficient A physician must be well-trained in the arts and science of medicine Zahalon continues, "He must be learned in the science of medicine He must be a man of experience in his work He must possess the power of persuasion smooth speech, which will appease the sick person 'His words have upheld him that was falling' (Job 4 4)"

Judging from his own expressions, Zahalon was convinced that his book supplied a great need "In some towns" he tells us, "there are no physicians, but there is a scholar who is able to understand and to study closely and to seek cures for the sick in this book Where the physician lives far from town and there is no time to be lost till he arrives, or again where several physicians visit a sick man and differ as to their treatment, the learned man can inform himself as to the valid and expert judgment of this book This book will likewise be of benefit to physicians themselves, who will find a 'table spread' for them without expounding differences of opinion at great length, as is the prevalent method of books of medicine I have only given the most proper, accepted and well-tried methods of cure Furthermore, this book

¹Quoted from Friedenwald's paper on Jacob Zahalon

¹Joel Ibn Shu Alb Rabbi preacher and commentator of 15th Century

will be of benefit to the poor who are unable to pay the fees of a physician. He will easily learn the treatment of his disease in this book. I shall go into detail concerning the more common diseases and I shall be brief in regard to others."

As for the style in which the book is written this is very interesting. Zahalon adopted for his medical work the legalistic method used in rabbinical literature, namely, that of the Responsa, or in the form of question and answer.

OUTLINE

Chapter I as listed above deals with General Hygiene. This is written for the well and the sick. In this chapter he describes minutely general rules in hygiene. For example he devotes a great deal of space to the importance of fresh air. Of course, in the present day with the various fresh air cults, radio lectures, fresh air schools, summer lakes we have become unimpaired. But remembering the time in which Zahalon lived and that superstition reigned supreme, and the primitive housing condition it is astounding indeed to find him with this modern viewpoint. Then he describes in detail the kind of water that is fit to drink. This was the age before chemistry and bacteriology so he gives us simple home tests to detect impurities in water. For example he advises the following simple experiment: Take two pieces of cloth of equal weight, put one in pure water and the other into the water to be tested. Then dry both pieces. If the water contains no impurities the weight of the two pieces of cloth when dry will be the same. Then he continues with the importance of exercise and relaxation. Following that he describes the rules of diet in detail. Of course, in these days we have all kinds of fads about dieting, the eighteen day diet, various reducing methods and particularly a flood of literature on vitamins, so what Zahalon has to say is not novel to us, but realizing that in those days when eating meant filling up the stomach as much as possible until one felt heavy and sleepy, Zahalon's advice is quite remarkable. He constantly advises that one should leave the table while still somewhat hungry. Now when it comes to the different kinds of food to eat, Rabbi Dr. Zahalon finds himself in his home territory. For whatever the origin of Jewish dietary laws may be they were all based on some hygienic principles.

In this chapter he summarizes the rules of hygiene by Maimonides. He concludes with an epistle by the Professors of Salerno to the King of England in regard to hygiene.¹ I shall quote

merely one passage that is of interest where Zahalon quoting them says, "If there is a lack of physicians, replace them with the following three, joyful thoughts, rest, and diet." In other words, the three wise, old physicians, Dr. Meriman, Dr. Rest and Dr. Diet, were as useful then as they are now.

In the second chapter he explains all kinds of fevers, their causes, signs and symptoms, and their treatment. At the end of this chapter he narrates the story of the Plague which occurred in Rome in June 1656.

Zahalon lived before the age of bacteriology, so he naturally did not know about bacillus pestis. But it is of interest to note what they actually did know and observe. He enumerates six causes of the plague:

- 1 Contaminated air as after a war, an earthquake, or flood, when dead bodies lie around on the ground.
- 2 The influences of the planets in accordance with the teachings of the astronomers.
- 3 Spoiled food such as is found during a famine, which is usually followed by the plague.
- 4 Poisons that contaminated the water supply.
- 5 Filth as observed from experience.
- 6 Contact with other people who suffer from the plague or with their clothes. This is particularly true when one is fatigued or weak.

Therefore, he advises "In times of epidemic keep away from crowds."

"Happy is he who is fearful and he that is stubborn will fall into evil." "One should also be careful about fresh air, good food, rest, relaxation, clean homes, and freedom from worry and aggravation."

In Chapter II he also wishes to prove how great is the effect of the imagination on the body so he narrates how a woman gave birth to a child whose abdomen was open and the intestines exposed and thus, he explains was due to the fact that the mother during pregnancy, passed by a meat shop and saw the butcher opening the abdomen and removing the contents of a calf. The power of her imagination affected her offspring in the same manner. This gives us a picture of certain beliefs in the Seventeenth Century.

Chapter III deals with the signs of the pulse, urine, and the tongue. He describes the mechanism of the pulse in detail and its variations. He mentions the regular and irregular pulse, the pulse where all beats are equal or when every other one or every third is unequal. Then he calls attention to the intermittent pulse where every third beat is skipped and the deficient

¹This is probably the "Regimen Sanitatis Salernitanum" said to be addressed by the School of Salerno to Robert of Normandy son of William the Conqueror. But this problem is still in dispute.

pulse, where there is a longer pause between the beats. This description of the pulse is picturesque in places. For example, he speaks of a pulse that jumps like a goat, and the one that feels, to the examining finger, like the ocean waves. "There is a pulse," he says, "like that of a worm, and then the tiny quick pulse like the ant, and the completely irregular pulse."

He also gives instruction to the physician on how to take the pulse. The examining finger must be soft, not hard, nor should it be too hot or too cold. The physician should not take the pulse as soon as he enters the house of the patient, for then the patient is frightened and the pulse changes, but he should allow him to rest a while. He should observe the pulse in both hands of the patient. The physician should feel the pulse with three fingers, and he should not press too hard so as to obliterate the pulse, nor too lightly, so as to miss the strength of the pulse. In a similar manner, he instructs the physician in the method of examining the urine of a patient. He finally concludes this chapter with the signs of the tongue, in case of illness.

Chapter IV deals with all kinds of poisons and their antidotes. He starts with a general discussion as to what is a poison, and whether it always damages the heart. He concludes that although some believe the latter, there are others who claim that every poison injures some particular organ. He divides the poisons into three classes, minerals, plants, and those in living organisms.

His discussion of mercury is very interesting indeed. He states that although physicians prescribe mercury in case of intestinal worms, yet it is injurious and kills. It injures the intestines and causes needle-like pain. At times it is accompanied by painful diarrhea, and a heavy feeling in the body. If it stays in the intestines too long, it causes retention of urine and the body appears like lead, there is a bad odor from the mouth, the hands are paralyzed, the heart is weakened, it blinds the eyes and paralyzes speech.

But what is even more interesting are his further observations. "These effects I have observed," he says, "not only when mercury is taken by mouth, but even when one rubs it on his head. Even the vapor of mercury will cause these bad symptoms, due to injury to the nerves and trembling and weakness of the limbs follow. There is damage to the senses, particularly to those of vision, hearing, constant headaches, falling out of the air, as it is observed among artisans in mercury." He continues, "These people have a marked salivation; the teeth become loose and there are ulcerations around the teeth. I have seen a patient who wanted to treat himself with medicine that contained mercury. I warned him not to, but he

finally did. The above lesions appeared in his mouth, followed by headaches. He died prematurely." The treatment of mercurial poisoning consists of enemas of olive oil mixed with chicken fat. The patient should drink a great deal of milk. But the best remedy is gold leaves, to be mixed with the food, which is specific against mercury. "I had this experience with the help of God—a young lady who rubbed her head with mercury and developed the above symptoms took leaves of gold, and blessed be the Lord, she was cured."

Especially interesting is his discussion of opium. Some physicians doubt whether it should be classed as a poison, others claim that it is a poison. Zahalon concludes that untreated opium is poisonous. "Although there are," he says, "habitual takers of opium to whom it is not injurious, this is no argument, since habit becomes second nature." He concludes, "Though a little may not kill, nevertheless every poison has its lethal dose. Opium causes a deep sleep known as a narcosis. It also causes pruritus and sweating of the skin. It diminishes the breathing, the eyes become darkened, and finally the motion of the limbs becomes confused." He brings this chapter to a close with a discussion of poisons caused by living organisms, snakes and mad dogs. In connection with the latter he observes that the incubation period of hydrophobia may be as long as a year or more.

Chapter V is divided into two parts—the first deals with the nature and temperament of man. The second part deals with signs and symptoms of diseases, and their prognoses. He starts out with a discussion as to whether medicine is an art or a science. "Although it is not positive at times," he claims, "yet it is a science, since it has the beginning of an accumulation of truths." He defines medicine as the science by which we study the elements of the human body in order to preserve and guard its health and regain it when it is lost.

Chapter VI is concerned with the treatment of disease, known as therapeutics. He describes simple and compounded remedies and their indications in various illnesses. He starts out in this chapter by stating that the physician should give general directions and instructions to all sick, and particular instructions in individual cases. "In every instance," he continues, "the physician must observe the following three rules—positiveness, speed, and pleasantness." He also emphasizes the importance of the patient's diet. This is followed by an alphabetical list of syrups and their uses, as well as pills, solutions, oils, ointments, etc. There is even a discussion on various baths. This chapter is a study in itself, for it gives us a clear picture of the state of medicine during his time. He finally concludes with a description of and the uses of various medicinal plants.

Chapter VII discusses specific diseases of the head, the eyes, the ears, the nose, and the tongue. Zahalon's time was no age of specialization. In each case he discusses the signs, causes and treatment. Here he gives a brief anatomical description of the organs of the body. This gives us an insight into the limitations of anatomy in the Seventeenth Century. For example he enumerates eight pairs of cranial nerves. Then he adds that there are thirty seven pairs of nerves that come from the brain through the spinal cord.

In one paragraph he discusses the treatment of "love sickness", which sounds like some of the modern psychoanalytical literature. This disease is recognized," he says "by the sinking of the eyes, and weeping like voice without tears. The patient's lids drop and are shaky and his pulse is rapid, like one who is troubled a great deal. His mental state is changed although he appears well otherwise." As for treatment it varies as follows: (1) To obtain the desired object, (2) or let him think of some fault in his sweetheart, (3) let him indulge in other higher interests, (4) let him change his place of residence and go to a large city where they will not meet, etc.

His first suggestion is obvious: let him do what we now call Rationalization, and his third Sublimation.

Chapter VIII deals with diseases of the throat: esophagus, trachea, chest, lungs, heart and diaphragm.

Chapter IX discusses diseases of the abdomen: liver, spleen, intestines, kidneys, etc. He concludes this chapter with a long discourse on hypochondriasis, because the liver or spleen was supposed to be the seat of this disease.

Chapter X contains a discussion of external diseases of the body and surgery. It treats briefly tumors, ulcers, fractures, dislocations, their causes and treatment.

Chapter XI deals with particular diseases of women.

Chapter XII is missing in this book, and Chapter XIII was not published, for lack of funds.

Throughout the book he mentions numerous Greek, Latin, Italian and Hebrew authors, which is sufficient material for a study in itself.

In this book, he describes conditions during the plague in the following quaint manner:

"In 5416 (1656) in the month of June, a disease called morbilli broke out among the children most of them died. Afterwards adults became ill with blotches on the skin called petechiae and in three days they were dead. It appeared three months earlier among the Gentiles than among the Jews. It also came to an end earlier among the Gentiles. The Jews were forbidden to leave the Ghetto and enter the city, as was their custom. Two officers were sent to the Ghetto to prepare a suitable 'Lazaretto' where the sick could be placed so that they

were separated from the healthy and thus prevent the spread of the epidemic. They ordered that the place selected for this should be the houses on the street along the river near the gate of the Ghetto known as the Gate of the Bridge, where they should be confined until cured. They appointed an officer, Monsignor Negroni, who came twice a day to look after the needs of the community and to enforce rigid isolation at a great penalty, they set up gallows near the gate to hang anyone transgressing these orders. They appointed a Gentile physician, who remained confined in the Ghetto, and who ordered everyone affected to be brought to the 'Lazaretto'. For the care of the patients in the 'Lazaretto' there were resident there the physician Samuel Gabbai (may the Lord preserve him!), and his father, Circio, who died while the son recovered. The lazaretto houses were divided into three parts, to each of which one Jewish physician was appointed.

"Blessed be the Lord who did kindness to me and preserved me and saved me in order to carry out His will. I raise the cup of salvation and call upon the name of the Lord. Praises be given to the Lord for He is good, for His mercy endureth forever.

"At that time it occurred to me that a certain patient whose name was Sabbatiah Cohen (of blessed memory) became ill with fever. He had a swelling in the groin and I did not consider it a bubo. When he died I stated that he did not die of the plague, but the Gentile physician said that he died of the plague because he saw the swelling in the groin which I regarded as a hernia of the intestines. There was therefore a great difference of opinion as to the closing up of the house, as was done when one died of the disease. They brought the body to the Gentile physician, opened it, and found that it was as I had said, and not a bubo as the Gentile physician had maintained, and I was saved. Blessed be he who redeems and saves!

This was the procedure. The Jewish physician visited the sick and if he saw any signs of the disease a black "caruncle" or a bubo in the groin with fever or other serious symptoms, especially if the tongue was white as snow, he would call the Gentile physician to examine the patient, the latter would order that they take the patient and his bed to the lazaretto to Samuel Gabbai—or the patient might remain home and be treated there.

"When the physician visited the sick it was customary that he take in his hand a large torch of tar burning at night and day to purify the air for his protection,* and in his mouth he had theriac. With God's help, it also aided me greatly that on my left arm I placed a seton, from which there flowed much blood and had pus.

* In the nine months, during which this epi-

It is possible that the vapor of the burning tar impregnating his clothes, made the doctor an undesirable host for fleas and thus afforded real protection.

demie lasted there died, both young and old, about 800, among them a young scholar expert in the science of surgery, Isaac Zahalon, my father's brother's son of blessed memory

"They brought the dead to the river in small boats and carried the bodies to the cemetery outside the city to a place called Piano dei devisori

"Since the people were not able to go to synagogue, on Sabbath Toledoth (Kislev 2, 5417) I, Jacob Zahalon, preached in Catalena Street, from the window in the corner house of David Gatigno, to the people (may God preserve them!), standing in the street. At another time I preached in Toscana Street, from the window of the house of Judah Gatigno (of blessed memory), the people standing in the street to listen to the sermon. In other streets scholars would preach from the windows of their houses

"None were permitted to go out on the street save physicians, except at certain times to get food, at night no one was allowed to leave his house. The guards patrolled the city and if they found anyone they would put him into a prison appointed for that purpose

"After nine months the Holy One (blessed be He) remembered His people because of the merit of their forefathers and the disease came to an end and they were well and the gates were opened and Israel returned to the synagogues to pray as in former times. Give thanks and praise to God on High, whose kindness never ceases and whose mercy never ends!"

Judging from his book, Zahalon was a great physician and scholar. One of his contemporaries, Nathaniel Segie, declared that Jacob Zahalon was one of the three most learned men of his generation

I have given you merely a short biography of the man and a sketchy analysis of his book. For the scholar, this book, like any book of the past, offers a wide field of research. In the first place who are the men he quotes in his book? He mentions a number of Latin, Greek, Hebrew and Arabic authors, whom he read either in the original or in Hebrew translations. He quotes from many documents, as for instance, letters written by the professors of Salerno to the King of England. We would like to know who these professors were. Then he quotes in Hebrew transliterations numerous medical terms in Latin or in Italian, which give us a clue to the medical sources and the medical vocabulary of that day. He translates these terms into Hebrew which is of great value to Hebrew medical terminology, particularly is it of value at the present time with the revival of the Hebrew language and the medical and scientific courses being introduced in the Hebrew University on Mt Scopus. He makes references to many popular practices and treatments which may be collected and studied to give us a picture of how the healing art was carried on in those days. It is a great book of information for the student of medical history.

In conclusion, I wish to state that we are very grateful to the Hvams Fund for providing us with these old Hebrew classics on medicine, from which we can draw a knowledge of the history of the healing art in the past and inspiration in our work in the present. These books, like their authors, wandered from place to place, until they were given shelter in the Boston Medical Library due to the expert knowledge, vision and indefatigable effort of its Director, Mr James F. Ballard

DO YOU KNOW?

QUICK ACTION is necessary in appendicitis cases. Statistics recently compiled on Philadelphia hospitals show that among those admitted within twenty-four hours after onset of symptoms, one in forty-six died; among those admitted forty-eight to seventy-two hours, one in fourteen died; and among those whose admission was further delayed, one in ten died.

MOST PEOPLE believe that there is a 'cure' for everything. They make the wish father to the thought. 'Master minds' of science, toiling through midnight hours in a feverish search for discoveries, is the romantic picture, false to reality, which leads the multitude to expect too much from research. Strangely enough, many of the most useful advances in science have come while investigators were looking for something else. Much remains to be learned about our natural environment, and we have not begun to penetrate the mystery of life itself. Nobody knows how to put his finger on the

precise point where the inanimate becomes animate, and how

THE FIRST bathtub in the United States was installed in a Cincinnati home in 1842. It was made of mahogany and lined with sheet lead. Newspapers denounced it as an undemocratic vanity. Boston, in 1845 made bathing unlawful except when prescribed by a physician. Virginia "soaked the rich" by taxing bathtubs \$30 per year—*Excerpts from a column sponsored by the Medical Society of the State of New York*

THE NEW YORK HOSPITAL PLAN

The executive director of the Associated Hospital Service of New York reported the expectation that the ten thousandth member would be enrolled July 11, on the three-cents-a-day schedule.

One hundred and twenty-seven hospitals are participating in this service.

The plan includes hospitalization to members, in case of accidents or emergency illness while on vacations, in any American hospital.

VERMONT STATE MEDICAL SOCIETY

LOW BACK PAIN CAUSED BY LUMBOSACRAL ABNORMALITIES*

BY MAURICE V. BELLEROSE, M.D.†

CONGENITAL variations in the general anatomical structure of the lumbosacral joint are now recognized as one of the definite and common causes of pain in the low back and lower extremities. During the year 1933 as many as 467 cases admitted to the New York Orthopaedic Dispensary and Hospital complaining of symptoms traceable to the lumbosacral region could be attributed directly to anomalies in this area. These figures are given in an effort to convey the relative importance and frequency of these anatomical defects as causative agents in the production of pain and disability. This is not an end result study, nor a consideration of differential diagnosis but merely a presentation of the usual clinical and roentgenographic findings with case histories.

Before explaining how these variations may give rise to acute and chronic backache I shall like to present a general clinical picture typifying them as a group.

Acute Backache

An *original* acute attack is usually associated with a type of injury which places severe stresses upon the lumbar region, such as the lifting of heavy objects in a flexed position, sudden twists and falls. Many times however the pain may be initiated by some apparently trivial movement, such as bending over a wash basin to brush the teeth, etc. Pain in the back may be severe sometimes so much so that the individual drops to the ground and is unable to rise for several minutes. It is usually more marked in the lumbosacral region with radiation down the posterolateral aspect of one or both legs. Sometimes the pain in the lower extremities exceeds that in the back. Less often it is referred to the region over the sacroiliac joints, buttocks, hips or coccyx. Referred pain may be either unilateral or bilateral, irrespective of the type of injury or anomaly.

Signs

The patient assumes a protective attitude, holding the spine rigid, partially obliterating the lumbar lordosis. The trunk is flexed at the hips, and a list of the trunk to one side may be noticed, causing a tilting of the pelvis and apparent shortening of one leg—the so-called sciatic scoliosis. The sacrospinal muscles are in marked spasm and stand out prominently.

There is tenderness over the spinous process of the fifth lumbar and its ligamentous attachments, but if board like rigidity is present, tenderness may be absent. There may be tenderness over either or both sacrosciatic notches, the sciatic nerve, and along the course of the superficial peroneal nerve. Occasionally tenderness is found over the tip of the coccyx, and may lead to the mistaken diagnosis of injury to that structure. Motion in the lumbar spine is limited, especially flexion and lateral movements, the enforcement of which will cause considerable pain in the lumbosacral joint and will frequently be referred to one of the previously mentioned areas. Flexion of the thigh with the knee fully extended, compression or separation of iliac crests, or forceful abduction or internal rotation of the thighs may cause pain in the low back.

Chronic Backache

The great majority of people suffering from these anomalies however, do not have so definite a history nor such marked symptoms and signs, their picture is more obscure. Fatigue, weakness, or dull ache in the low back, with or without radiating pain may be the only complaint, usually appearing after mild exercise, or after sitting or standing for a moderate length of time. More often they have repeated subacute attacks of pain which are relieved by rest but which recur with increasing frequency and severity. The duration of the pain, the disability, and the rest periods becoming progressively longer, and the periods of relief correspondingly shorter. These attacks are often associated with some particular type of movement and may be accompanied by a sensation of something slipping or giving way in the joint. Sometimes the only complaint is pain, with or without paresthesia along the outer surface of the thigh and leg. It is advisable to examine the spine carefully in such instances in order to rule out the presence of lumbosacral defects, since it is believed that in the great majority of cases the cause of sciatica is a lumbosacral abnormality. It is the general opinion among neurologists that a primary neuritis of the sciatic nerve is a rarity.

The signs in these cases are the same as in the acute cases but less marked.

Roentgenographic examination is of invaluable assistance in establishing a diagnosis, without it, it would be impossible to detect the presence of skeletal anomalies. To demonstrate this

*From a study at the New York Orthopaedic Hospital Read before the Vermont State Medical Society at its Annual Meeting held in Burlington, Vermont, October 4 and 5, 1934.
†Bellerose, Maurice V.—Orthopaedic Surgeon, Rutland Hospital. For record and address of author see "This Week's Issue," page 183.

line of weight thrust passed well within the first sacral body. He was treated conservatively for one month, at the end of which time he was free from symptoms.

His rapid recovery was probably due to his good muscular development, which was able to compensate for the defective mechanics at the lumbosacral joint.

Spondylolisthesis (Anterior displacement)

As has already been stated, posterior displacements of the fifth lumbar body on the sacrum most often occur with anteroposterior or the rudimentary type of facets. Anterior displacements of the fifth lumbar on the sacrum can occur only when there are developmental defects in the neural arch, that is, failure of fusion of the pedicles to the body, the pedicles to the laminae, or the laminae to one another.

Eleanor S was a girl of thirteen years who came to the clinic because of a lateral curvature. She had never had symptoms referable to the low back. Although one-half inch anterior displacement of the fifth lumbar was present, together with defects in the laminae of the fifth lumbar and the first sacral vertebrae, the patient was symptom free. Evidently her soft tissue structures were able to compensate for these marked defects. This patient is very young, and will undoubtedly have trouble later because of the poor mechanics at the lumbosacral junction with the additional strain of a lateral curvature.

Long Spinous Process

James D, aged twenty-eight, was a case rather unusual in type of anomaly present and also in the kind of treatment which gave relief.

The skiogram shows an exceptionally long spinous process of the fifth lumbar with a defect in the posterior elements of the sacrum, forming a slot to receive it. The long spine is due to fibrous union of the tip of the first sacral spinous process to that of the fifth lumbar. The patient had a seven months' history of intermittent pain in the right hip, sometimes radiating down the leg, across the lower abdomen, and up to the upper lumbar area, but never in the low back. It may be that the tip of the long spinous process pressed upon the meninges when the spine was extended, causing irritation of the meninges and giving rise to impulses which passed through the afferent fibres of the sympathetics to the posterior roots of the first and second lumbar nerves. This might account for the peculiar distribution of the pain, since these nerves supply sensation to the parts mentioned. It was found that the patient had a three-quarter inch shortening of the right lower extremity, which was equalized by removing lifts from one heel and adding to the other. This simple procedure gave complete relief from symptoms.

Transitional Vertebrae

I have previously mentioned that the lumbar spine is undergoing evolutionary changes. This manifests itself in the trend of the lumbar spine to become shortened, that is, to have four lumbar vertebrae instead of the usual five, the fifth becoming incorporated in the sacrum. In some instances the fifth lumbar is in a state of transition and becomes only partially sacralized.

Mr M, aged twenty-one, and in good health, had a transitional type of fifth lumbar vertebra.

The lateral process on the right is of the sacral type and forms a false joint with the ala of the sacrum, this is obviously a poor mechanical arrangement. The patient complained of a queer sensation in the right thigh and knee. Four years ago he had slight pain in the region of the right great trochanter, which has gradually extended itself down the outer side of the thigh to the knee. This he described as being more "a tired feeling" than an actual pain. The muscles and ligaments of the thigh felt stiff and tired easily. Although the pain complained of began four years ago and persisted intermittently in the right iliac crest region and the lateral side of the right thigh, not until six months ago did it become frequent. Since that time it has been constant and more severe. Lately the patient has been suffering from a slight pain over the fifth lumbar vertebra and in the posterior aspects of both thighs.

He was treated conservatively for seven months with heat and massage and wore a lumbosacral belt, without relief of symptoms. Physical examination was negative. Spine fusion is being considered.

Sometimes the transverse process becomes fused to the ala of the sacrum on one or both sides. Unilateral fusion of the lateral mass to the ala of the sacrum sometimes causes strain upon the opposite facet with resultant pain and disability.

General Treatment

The underlying principle of treatment is relief of symptoms by immobilization. This may be procured by two methods: 1. Conservative, 2. Operative.

Conservative treatment is always used in original, acute and infrequent attacks. If the attack is very painful and disabling, the patient is given complete bedrest for from one to three weeks. It is important that the bed be hard, that is, one which does not sag. Such a bed can be made in the home by placing longitudinal boards between the springs and mattress. The low-back is firmly strapped with adhesive tape from mid-sacrum upwards so as to include the lower ribs, care being taken that some of the strips are well anchored to the anterior borders and crests of the ilia. A small pad beneath the tape pressing over the lumbosacral joint sometimes gives added relief. Dry heat may be applied to the part, but in some cases it aggravates the pain. After the muscle spasm and acute tenderness have subsided, massage is indicated.

The patient is then gradually allowed out of bed in a snugly fitting lumbosacral belt of heavy canvas, which has a rhomboid-shaped pad on its skin surface pressing over the lumbosacral joint. The belt should be worn as short a time as possible, the patient leaving it off an increasing length of time daily, until it is no longer needed. One of the most important factors in the convalescent treatment is *educational exercises*. They increase the flexibility of the spine, strengthen the ligamentous and muscular

lar structures, and help correct any postural defects. These exercises should be done under competent supervision.

In the milder and infrequent attacks of low back pain, strapping followed by massage and exercises are usually all the treatment necessary.

Operative Treatment

In many cases conservative treatment is insufficient, but if pain and disability persist, or recur at short intervals, operative treatment should be resorted to.

The operative procedure, as used at the New York Orthopaedic Hospital is fusion of the fifth lumbar vertebra to the sacrum by the Hibbs method, which has proved to be very satisfactory in relieving symptoms where the conservative measures have failed, because it absolutely immobilizes the lumbosacral joint. This operation does not appreciably hinder mobility of the spine as a whole, since there is normally motion of only five degrees in this joint.

Cases in which the lumbosacral articulations are asymmetrical or in which the fifth lumbar is partially sacralized are particularly likely to be unresponsive to conservative measures. In spondylolisthesis the spine should always be fused, and in this anomaly, of course, the fusion is extended from the fourth lumbar vertebra to the sacrum.

Fusion operations upon the spine are regarded by many surgeons as an extensive, radical and dangerous procedure, but statistics prove otherwise. Up to 1927, as many as 150 lumbosacral fusions were done in the New York Orthopaedic Hospital with no deaths or instances of postoperative shock. Since that time over 200 more have been done with the same results.

Before concluding this paper, I should like to pay tribute to the genius of the late Dr. Russell A. Hibbs, who first devised the spinal operation for tuberculosis of the spine and who later was the first to apply it to lumbosacral abnormalities. This opened an entirely new field in the treatment of these conditions, and made it possible to restore to normal activity many individuals who otherwise would have remained permanently handicapped.

SUMMARY

1. Congenital anatomical variations in the lumbosacral joint increase the mobility at the expense of stability.
2. Instability of the lumbosacral joint causes strain upon the supporting soft tissue structures and articular facets.

3. The most common causes of so-called sciatica are anomalies in the lumbosacral region.

4. Conservative treatment is based on an attempt to decrease the degree of mobility of the lumbosacral joint and to improve the relationship between the fifth lumbar and the first sacral vertebra. When this fails to give adequate relief from symptoms, the lumbosacral joint may be completely stabilized by the Hibbs spine fusion operation.

RECENT DEATHS

WATSON—HORACE L. WATSON, M.D. aged seventy two died at his home in Montpelier Vermont May 19 1935 after an illness of three months.

Dr. Watson was born on October 22 1862 at Worcester Vt., the son of Oliver and Nancy Darling Watson. He was educated at Barre Academy and at the University of Vermont graduating from the medical school in 1887. Before coming to Montpelier he practiced at Plainfield N. H., Hartford and West Topsham Vt. He studied at intervals at the College of Physicians and Surgeons in New York.

He was a member of the Odd Fellows the Knights of Pythias the Delta Mu Fraternity at the University of Vermont, and the Washington County and Vermont State Medical Societies.

Dr. Watson is survived by his wife Mary S. Watson, whom he married at Plainfield in 1890, two of their three children, Dr. Harold L. Watson of Montpelier and Mrs. Marian E. Burgess of Brookline Mass., two grandchildren and a sister Mrs. D. C. Hayes of Waterbury Center Vt.

PIERCE—WALLACE M. PIERCE, M.D., died suddenly at his home on Main Street, Burlington Vermont, June 3 1925. He was born February 17 1872 the son of Lemuel and Luella Armstrong Pierce.

Dr. Pierce was graduated from Brigham Academy and from the University of Vermont Medical College in 1898. He then began the practice of medicine in Middlebury Vt., later going to Providence R. I. He had been a sales representative for the Abbott Laboratories of New York and Chicago for the past twenty three years.

Dr. Pierce was a member of Washington Lodge No. 2 and A. M. Burlington Chapter No. 2, R. A. M. Burlington Council No. 5 R. and S. M., Burlington Commandery No. 2, K. T., Haswell Lodge of Perfection J. W. Roby Council P. of J. Delta Chapter of Rose Croix Vermont Consistory A. A. S. R. Klismet Temple No. 98 A. A. O. N. M. S. of Brooklyn New York.

Dr. Pierce is survived by one son Francis, of Long Island N. Y. and a grandson.

TRACY B MALLORY, M.D., *Editor*

CASE 21301

PRESENTATION OF CASE

A forty-four year old Canadian housewife entered complaining of weakness and severe headache of seven weeks' duration

The patient stated that her symptoms began following a hemorrhoid operation seven weeks before entry. Upon further questioning, however, her history dates back to three years before entry when she had sore gums and tongue associated with vague indigestion and gas. At that time she ate only a small amount of meat and lived for the most part on green foods. One and a half years before entry she noticed numbness of her hands, more marked on the left, which was soon followed by a similar feeling in her toes. Since then she had considerable fatigue and slight shortness of breath upon exertion during the past eight months but no other symptoms. Following the hemorrhoidectomy she began to have increasing weakness and excruciating headaches from which she could get no relief. Two weeks before entry she visited her physician who told her she had anemia for which he prescribed liver and iron.

Her family and marital histories are non-contributory.

Physical examination showed a very pale, fairly well-developed and nourished woman complaining of headache. Her skin was sallow and the sclerae were white. The tongue was smooth on both lateral edges. The fundi showed petechiae and flame shaped hemorrhages. The heart, lungs and abdomen were negative. The blood pressure was 100/60. A neurological examination was negative except for absent abdominal reflexes and hyperactive left knee jerks.

The temperature was 100°, the pulse 120. The respirations were 25.

Examination of the urine showed a specific gravity of 1.010 to 1.020 and a sediment containing numerous epithelial cells. The blood showed a red cell count of 1,150,000, with a hemoglobin of 40 per cent. The white cell count was 1,200. A smear showed poikilocytosis and anisocytosis but no achromia. A differential count showed 28 per cent polymorphonuclears, 32 per cent lymphocytes, 28 per cent myelocytes, 4 per cent myeloblasts, and 8 per cent

large mononuclears. Platelets were seen in very small numbers. The stools were negative. The icteric index was 5. The van den Bergh was normal. The nonprotein nitrogen of the blood was 21 milligrams. The serum protein was 6.4 per cent. A gastric analysis showed no free hydrochloric acid. The bleeding time was 30 minutes.

X-ray examination of the chest and abdomen was negative.

On the fourth day she was given a transfusion of 600 cubic centimeters of whole blood with immediate relief of her headache, and the following day 3 cubic centimeters of liver extract intramuscularly. She did not respond to liver. During the third week information was received from her family that the patient had worked in a rubber factory with benzol for four years until one month before her present illness. She was given repeated transfusions followed by a very slow rise in her red blood cell count. After being in the hospital for one month her red blood cell count was 2,650,000, with a hemoglobin of 60 per cent. The white cell count was 2,800, 53 per cent polymorphonuclears, 42 per cent lymphocytes and 5 per cent large mononuclears. Very few platelets were seen. She developed numerous ecchymotic spots all over her body and several petechiae appeared on the soft palate, tongue and inside of the cheek. Because of excessive vaginal bleeding she was sterilized by x-ray during the sixth week. During the ninth week she developed areas of subcutaneous induration over the left forearm and upper arm. A few days later similar lesions appeared over her legs and trunk. She was having chills every afternoon with fever as high as 104°. During the eleventh week she developed right lower quadrant pain, vomiting and bloody diarrhea. Her white blood cell count reached 6,000. She was critically ill for ten days but gradually improved. During this period there developed a very tender mass in her right lower quadrant which disappeared as her condition improved. Transfusions were continued. She began passing considerable blood in her urine and stools. The subcutaneous lesions increased in number. Her red blood cell count at the beginning of the fourth month had reached 3,500,000. The reticulocyte count was 0.5 per cent. Toward the end of the fifth month she complained of right upper quadrant pain, abdominal distention and pain in her fingers. Both hands became swollen, blue and hemorrhagic. Her white cell count steadily fell and she finally died five months after entry after having received forty transfusions.

DIFFERENTIAL DIAGNOSIS

DR. CHARLES L. SHORT. The history as given on the patient's admission is certainly that of a progressing anemia of at least one and a half

years' duration. The fact that she ate only a small amount of meat is of interest but seems of minor importance in view of the severity of her anemia. Similarly, the numbness of her hands is merely a symptom of severe anemia without necessarily suggesting the diagnosis of pernicious anemia. The fatigue and headache are all compatible. The physical examination is not significant except for pallor and retinal hemorrhages. Her blood showed a severe anemia, tending toward a high color index. We are not told about the size of the cells. It would be interesting to have a volume index. There is no sign of regeneration of the red cells as evidenced by the peripheral blood. There was severe leukopenia with absolute decrease of all the elements. Twenty-eight per cent myelocytes may signify that there is some regeneration going on in the granulocyte series. The markedly diminished platelets and the prolonged bleeding time perhaps foreshadow the hemorrhages during her stay in the hospital. The normal icteric index and van den Bergh gave no evidence of any peripheral red cell destruction.

To sum up, we have a patient with symptoms of anemia for at least a year and a half presenting pallor and retinal hemorrhages. From a therapeutic viewpoint the first thing to determine would be whether she had pernicious anemia. If so, the smear should show at this level of red cells more characteristic forms in the erythrocytes, and we would expect more mature polymorphonuclears. We should also expect to have some evidence of peripheral blood destruction. We should not expect to find the prolonged bleeding time. The retinal hemorrhages and the achlorhydria are compatible with this diagnosis. At this point I should say that the evidence was distinctly against pernicious anemia but that she very properly got a therapeutic test with intramuscular liver. The failure of the patient to respond in the absence of sepsis or some other complication completes the elimination of pernicious anemia as a diagnosis.

Next, I think the diagnosis of primary thrombocytopenic purpura is unwarranted in view of the severe anemia and leukopenia with the lack of history of hemorrhage up to this point.

Aleukemic leukemia is suggested by the presence of myelocytes but we hear nothing more about them in the repeated blood examinations which were undoubtedly done during the next five months while the patient was on the ward, so I think we can rule out this diagnosis.

We are told that the patient worked in a rubber factory with benzol for four years until one month before the present illness. I think that this information gives the clue as to the etiological diagnosis and renders further discussion of the differential diagnosis unnecessary, including such things as primary aplastic anemia and malignancy. We know exposure to benzol will produce aplastic anemia, which is often fatal,

with depression of all three elements of the bone marrow either simultaneously or successively. We know that the process will go on in the bone marrow for many months sometimes, even though all exposure to the poison has ceased. In this case she had apparently stopped working in the factory about three months before entry to the hospital. At that time she had well marked symptoms of anemia. We do not know just how much exposure she had to benzol. We do not know the conditions in the factory. We do not know whether the other workers had symptoms of anemia. There is marked variation in susceptibility to this drug and it is possible that she was the only employee who was suffering from any obvious anemia. We see a similar individual hypersusceptibility in two other drugs which occasionally cause marked damage to the bone marrow, arsphenamine and amidopyrin. In the case of benzol one difference is that the lesions can be pretty regularly reproduced experimentally in animals if the proper dose is given. The severe headaches that the patient had seem to be a rather consistent symptom of this form of poisoning. I do not think there is any doubt that she was suffering from benzol poisoning. The myelocytes may represent some regeneration going on along with the aplasia as we know that this may precede or follow it, both in animals and in man. In fact a few cases of hyperplastic marrow have been found at autopsy with or without signs of regeneration in the peripheral blood.

This patient was treated by repeated transfusions which, as far as I know, constitute the only worthwhile method of treatment. I believe Dr. Jackson has treated a few milder, more chronic cases with nucleotide with apparently some increase in red cell regeneration but I do not know of any severe cases being treated successfully by this method. It was certainly very worthwhile in this case to continue with the transfusions since, if the patient could be carried along, at any time the bone marrow might start to show some sign of regeneration and the patient might be saved. The transfusions apparently restored her to a certain point as indicated by her red cells and leucocytes, but had little influence on the bleeding tendency, which was undoubtedly maintained not only by the scanty platelets but by increased capillary permeability.

The subcutaneous indurated areas I should interpret as hemorrhages under the skin or in the muscles. Chills and fever in the absence of obvious sepsis are commonly described in benzol poisoning and are said to be of serious prognostic omen. Of course they may represent some undiscovered infection and the question next arises whether the patient did have sepsis or whether the whole picture was due to benzol poisoning. We know that the resistance to infection is depressed in benzol poison-

ing Without further definite evidence, however, I do not think we have any right to conclude that she did have sepsis although a septicemia, endocarditis or pneumonia is possible

The right lower quadrant mass which disappeared I should interpret as intraperitoneal hemorrhage, as well as the final right upper quadrant pain of which the patient complained "The hands became swollen, blue and hemorrhagic" I should think this was probably due to hemorrhages in the subcutaneous tissues and in the muscles

I believe, then, that this patient died of benzol poisoning with bone marrow aplasia and a marked bleeding tendency I think that generalized hemorrhages will be a striking finding at autopsy She probably had an aplastic bone marrow since she shows so few signs of regeneration in the peripheral blood However, the peripheral blood does not always accurately reflect the state of the bone marrow and it is possible that she will have a hyperplastic marrow, representing a state of arrested maturation

CLINICAL DISCUSSION

DR WALTER BAUER From the occupational history we obtained information which of itself was very suggestive that we were dealing with an individual suffering from benzol poisoning However, in order to be more certain of our diagnosis, some of the material used in the factory was obtained for analysis Its physical properties were similar to those of benzol This additional evidence seemed to leave little doubt as to the correctness of our diagnosis

In this clinic we have never had anyone live this long and eventually recover However, such cases are reported in the medical literature One mild case of chronic benzol poisoning reported from Guy's Hospital was transfused repeatedly over a period of two years with ultimate recovery Coming back to this patient, it is interesting that the only time she had a nearly normal white count was following the intra-abdominal hemorrhage At this time the white count went to 6,000 Someone suggested at that time that she be given fever therapy in the hope that it might be maintained This, however, seemed too dangerous to think of undertaking All the time she was on the ward we wondered whether we should take a biopsy in order to be absolutely certain that we were dealing with benzol poisoning and not with some other form of aplastic anemia We transfused her repeatedly in the hope that her own bone marrow would start manufacturing red blood cells before she succumbed to some intercurrent infection Because she had been treated enthusiastically and had failed to respond we did at times wish that we could see a section of the bone marrow However, the risk of serious bleeding or secondary infection seemed too

great and therefore it was never undertaken I do not think one can fully appreciate just how much work the house officers did in treating this woman They finally ended up by doing transfusions using the veins of the neck I think if it had not been for their enthusiasm she would have succumbed much sooner than she did

CLINICAL DIAGNOSIS

Aplastic anemia due to benzol poisoning

DR CHARLES L SHORT'S DIAGNOSIS

Aplastic anemia due to benzol poisoning

ANATOMIC DIAGNOSES

Aplastic anemia (benzol poisoning)

Typhlitis, acute and chronic

Gas bacillus septicemia

Septic staining of aorta, endocardium and pulmonary artery

Bullous lesions of the skin

Decubitus

Peritonitis, chronic localized

Hemorrhage into right renal pelvis and ureter

Hemopericardium, slight

Cholesterosis of the gall bladder, slight

PATHOLOGIC DISCUSSION

DR TRACY B MALLORY The autopsy in this case showed all that one could expect a case of chronic benzol poisoning to show In other words the bone marrow was practically completely aplastic There is nothing pathognomonic about the picture We cannot tell the difference between aplastic anemia due to benzol and the so-called primary aplastic anemia, if there is such a thing The immediate cause of death as it is so often in these cases was sepsis The record gave no adequate indication of its character She developed a generalized septicemia with *B. Welchii* and in the short intervening period between death and her arrival at the morgue the body had blown up to an almost unrecognizable form There were bullae four and five inches in diameter filled with gas scattered throughout the subcutaneous tissues and deeper organs Most of that gas-formation undoubtedly occurred postmortem so that the record could not well have shown it

Dr Short was speaking of experimental work in benzol poisoning I think perhaps a word is in order there It is quite true that lesions can be produced with regularity in animals with adequate doses of benzol but by and large they are not very typical of lesions seen in man The effect in animals is much more on the white cells than the red cells In man that may be true of individual cases but on the whole anemia is a fairly constant feature The great majority of cases of benzol poisoning show at autopsy an aplastic marrow There are a few cases re-

ported with a hyperplastic marrow and you can reproduce a similar stage in animals with proper dosage.

A PHYSICIAN What percentage of cases of benzol poisoning recover?

DR. F. B. HUNTER It is rather hard to say. We had six here some years ago that got well. Interestingly enough the ones that died all had white counts below 1200 and all had fever. Since then we have looked upon fever in these people from the onset as an unfavorable sign.

A PHYSICIAN Did you find anything to account for the episode in the right lower quadrant?

DR. MALLORY The cecum was distended and the walls somewhat thickened. It raised a question in our minds of primary typhilitis due to gas bacillus. I have heard of two such cases.

A PHYSICIAN That was many weeks before.

DR. MALLORY That makes it seem improbable. The organs were so distorted by gas bubbles that it was pretty difficult to recognize any minor changes.

CASE 21302

PRESENTATION OF CASE

First Admission A fifty-three year old German housewife entered complaining of abdominal swelling of two and a half months duration.

Approximately eight months before entry the patient noticed edema and shooting pains in her legs. She believed that this condition was the result of varicose veins, which she had had for years, and at that time began to have the veins injected at another clinic. After the fifth injection, approximately three months before entry, her sclerae became yellow. Two and a half months before entry the swelling of her legs increased and soon after that she noticed that her abdomen was getting larger. Two months before entry she became nauseated every morning and vomited sour yellowish fluid following which she felt much better. She also noticed a dragging sensation in her lower abdomen and in addition a feeling of pressure in the left upper quadrant which was relieved by pushing her hand against that region. Her abdomen continued to increase in size and the edema of her legs also increased. Two and a half weeks before entry her physician removed two and a half gallons of fluid from her abdomen, and five days before entry removed about four gallons. Following each tap the abdomen immediately swelled again. Her urine had been scant in amount. The stools were normal in color.

Her family and marital histories are non-contributory.

She had worked as a cook and a maid until seven years before entry. From a very early

age she had drunk wine or beer nearly every day and occasionally a little hard liquor. She stated that she had never had enough to make her intoxicated at any time, though her friends asserted she would frequently drink a quart of whiskey in an evening.

Physical examination showed a well-developed and obese woman lying in bed with some respiratory embarrassment. The lips were slightly cyanotic. The skin and sclerae were jaundiced and there were spider angiomas over both shoulders. There was slightly pitting brawny edema over the back, sacrum, thigh and legs. The lower half of the right chest was flat to percussion and showed bronchial breathing, absent tactile fremitus, egophony and a few rales. There were also a few rales in the left base. The heart was in a transverse position due to the high diaphragm. No murmurs were heard. The blood pressure was 154/68. The abdomen was bony, tense and markedly distended. An umbilical hernia was present. There were enlarged veins over the epigastrium. There was a definite fluid wave. No organs or masses were felt.

The temperature was 98.4°, the pulse 100. The respirations were 24.

The urine was dark brown in color and had a specific gravity of 1.014 to 1.024 and a very slight trace of albumin; there was no bile present. The sediment contained one to five white blood cells and five to ten red blood cells. The blood showed a red cell count of 3,250,000, with a hemoglobin of 70 per cent. The white cell count was 6,100, 79 per cent polymorphonuclears. The stools were brown in color and contained no occult blood. The Hinton test was negative. The nonprotein nitrogen was 27 milligrams per 100 cubic centimeters. The liver function test showed 90 per cent retention, the icteric index was 75. The van den Bergh was 8.77 milligrams per 100 cubic centimeters direct.

An abdominal paracentesis on the day of admission yielded 16½ liters of yellowish, slightly blood tinged fluid with a specific gravity of 1.005. Following this the spleen was felt and the liver edge also, just below the costal margin.

She was given intravenous salyrgan on the second and fourth days followed by theobromin, 30 grams a day. On the sixth day a note was made that she weighed 47 pounds less than at entry. The edema of her lower extremities had cleared up remarkably well. Two days later she became slightly irrational and on that day 7½ liters of fluid were removed from the abdomen. She improved somewhat but the ascites reaccumulated. On the eighteenth day 6 liters of fluid were removed. She was discharged approximately one month after admission to return to the Emergency Ward for abdominal paracentesis and to remain on potassium iodide solution, 5 drops three times a day.

Second Admission, seven weeks later.

She remained fairly well after discharge but

THE DOCTOR'S BILL

At a time when there is so much loose talk about State medicine it is good for us to have as sound a discussion of the factors involved in medical economics as Hugh Cabot gives us in "The Doctor's Bill".* Beginning his book with a delightful chapter on medical practice in 1890 and 1930 Doctor Cabot, in the salty phraseology which we associate with him proceeds to analyze the chief features of medical practice to-day. In this study which is satisfactorily thorough as to the facts presented and is interspersed with the author's comments on these facts, Doctor Cabot includes the requirements of modern medical diagnosis, our medical resources (the training of medical students and of nurses and the development of hospitals), the relation of specialism to general medicine, various types of group health services, workmen's compensation acts, the ability of the public to pay for medical services, and a résumé of the methods employed by

other countries, notably Great Britain and Germany, in meeting the situation

Following his presentation of the principal factors involved in the problem, Doctor Cabot suggests various ways in which medical practice in the United States might depart from its present status. His own attitude may be inferred from the following quotation "It should be remembered, however, that the decision as to what pattern medical practice will gradually assume will not be made, in the long run, solely upon the opinion of the profession. In this field physicians have no exclusive rights to the expression of authoritative opinion. The problems are economic and social, rather than technical and professional. In the long run, the decision must remain with public opinion, since, after all, it is the public, and not the profession, which is most vitally concerned. I cannot subscribe to the view that any group in the community has any rights which the public is bound to respect, if they can be shown to be opposed to the public interest."

That this attitude is essentially sound seems to us to be obvious. The logical conclusion is that if any measure can be found which will provide better medical care for a larger number of people, this measure should be incorporated in the practice of medicine.

Doctor Cabot does not attempt to tell us the answers to the questions which he has suggested. Instead, he indicates possible solutions, and gives his views as to their practicability. Since he offers no panacea, it is difficult to give in abstract the conclusions at which he has arrived, more particularly so because he leaves us with the suggestions instead of the conclusion. One gets the impression that he would favor experimentation by various localities with various methods of voluntary insurance. Compulsory insurance in this country he believes would prove unsatisfactory. He would favor the regulation of specialists, but unlike many writers, he believes that the growth of true specialism is good and not harmful. He prefers a National Registry for doctors, such as exists in England, to the individual State Boards such as we have here, and finds much that is good in group health services, such as those organized by some universities and industrial corporations. As regards group medicine itself, Cabot says, "It appears to me to be of the first importance that we should consider very carefully the ultimate possibilities of group practice, particularly if we look forward to the development in this country of some plan which is suited to our own state of social progress, and is based upon developments which have already taken place here. It should not be forgotten that the development of the group is not only peculiar to this country but is the single outstanding contribution

*Published by Columbia University Press Columbia University New York, New York. 1935 313 pages

of the medical profession to improved organization for the delivery of medical service"

In effect, Cabot's only advice is that we should not oppose new departures just because they are new "On the part of organized medicine, too great an insistence on the perpetuation of the present order is in danger of developing into a struggle for the perpetuation of a vested interest." His book is suggestive, not conclusive, but it contains much material which can be employed in building a road out of the somewhat unstable region in which we now are, to higher and more solid ground

PUBLICITY BY A MEDICAL SOCIETY

The Public Relations Bureau of the Medical Society of New York has engaged in the distribution of short pithy articles to newspapers throughout the State of New York. Some of the subjects referred to for several weeks are "Baby's Care During the Summer", "The Titlo Doctor", "The Heart", "Sunburn", "Use of Honey", "Criminals", "Motor Accidents", "Summer Campers", "First Aid" "Swimming", "Fruits", "Rabies", "Ice Water" and "Accidents"

Publication is restricted to New York newspapers. The information is pertinent and presented in this way, is valuable for the information of the laity. Every state medical society might follow this custom to advantage, both because of its instructive features and as a demonstration of the interest of the society in the problems of preventive medicine

MISCELLANY

APPOINTMENT OF DR. JAMES W. MANARY

Dr. James Westcott Manary has been appointed to the position of Superintendent of the Boston City Hospital. He has served as Director of the Out Patient Department for several years and during Dr. Dowling's illness served as Acting Superintendent.

Dr. Manary was born in 1884 in South Boston and graduated from the Tufts College Medical School in 1908. He is a Fellow of the Massachusetts Medical Society and the American Medical Association and is very popular with the profession.

The report is current that Dr. Manary has assured His Honor Mayor Mansfield that every effort will be made to correct all irregularities which were alleged in the Boston daily papers to have existed.

The size and importance of the hospital with its staff of eminent physicians will have an inspiration to the new superintendent to maintain the traditions of this great municipal institution.

DR MARION DORSET DEAD

A brilliant scientific career devoted to public service was ended with the death of Dr Marion Dorset July 14 at his home in Washington, D C, after an illness of a few days. As a research worker in biological chemistry and chief of the Biochemic Division, Bureau of Animal Industry, U S Department of Agriculture, Dr Dorset gained an international reputation for contributions having useful application in the livestock, meat and dairy industries, and in public health.

On the occasion of his discovery of anti hog cholera serum, Dr Dorset had the opportunity to acquire wealth through the manufacture and sale of this product for which a large demand promptly developed. But after applying for and receiving a patent, he gave it to the Government and to the public so that any person in the United States might use the method without the payment of royalty—*U S Department of Agriculture*

APPOINTMENT OF DR MARTIN EDWARDS

Mr T Grafton Abbott, President of the Board of Directors of the Boston Young Men's Christian Association, has appointed Dr Martin Edwards to assist in the development of the guidance program for 1935 1936.

Dr Edwards was the former Dean of the Harvard Medical School of China.

PETER BENT BRIGHAM HOSPITAL

ANNUAL REPORT

The twenty-first annual report of the Peter Bent Brigham Hospital, for the year 1934, records a slight increase in bed occupancy over the preceding year, from 4,263 to 4,358. The percentage of free patients fell, largely due to an increase in part-pay patients, rated at \$2.10 a week. Actually, the receipts from patients in the open wards were less than for the previous year. The daily per capita cost of patients' care was \$7.15 as compared with \$7.60 in 1933.

The slight increase in operating expenses of the hospital was offset by an increase in receipts of \$36,492, so that, for all purposes, the treasurer was called upon for \$25,833.69 less than in the previous year.

The chief problem of the hospital, as of most privately organized institutions during these years, has been a financial one. However, its services are indispensable, and there is little question but that ways will continue to be found to meet its needs.

MORTALITY RATES

Telegraphic returns from 86 cities, with a total population of thirty-seven millions for the week ending June 29, indicate a mortality rate of 10.5, as against a rate of 10.8 for the corresponding week of last year. The highest rate (19.4) appears for Memphis, Tenn., and the lowest (5.1) for Waterbury, Conn. The highest infant mortality rate (170) appears for Knoxville, Tenn., and the lowest for Hartford, Conn., Miami, Fla., New Bedford, Mass., Port

land, Oreg., San Diego, Calif., Somerville, Mass., Tacoma, Wash., Trenton, N J., and Yonkers, N Y., which reported no infant mortality.

COMPARATIVE FIGURES FOR THE FIRST HALF OF 1935

The annual rate for 86 cities is 12.2 for the twenty-six weeks of 1935, as against a rate of 12.1 for the corresponding period of the previous year—*Bureau of the Census*

A BIOGRAPHY OF DR WILLIAM H WELCH

An announcement in the *New York Times* concerning the retirement of Dr Simon Flexner from the Rockefeller Institute states that he will "write the life of Dr William H Welch, with whom he studied and taught in Johns Hopkins."

CORRESPONDENCE

THE FAMILY PHYSICIAN AND PREVENTIVE MEDICINE

Editor, *New England Journal of Medicine*,

At the recent meeting of the State Society there was an excellent symposium on modern preventive measures of communicable diseases. One was impressed by the excellent work that has been done by the State Department of Health in its careful study of these measures and in making available to the physicians of Massachusetts the most modern material to use in the prevention of these diseases.

It was also apparent that there is considerable variation in the reactions of different individuals to these procedures as well as variations in the methods in which they may be applied to suit the individual. It seems obvious that they should be much more widely employed by the family physician in his private practice. He should not only employ these specific immunological procedures in protecting his patients, he should also seize the opportunity to advise other preventive and corrective measures which the individual requires.

In this part of the State for the past several years the Health Department has had practical monopoly of vaccination against smallpox and immunization against diphtheria. This is probably due in part to the enthusiasm of the Health Department nurses and their desire to make the work a success, and in part to the lack of interest of the average physician, or his fear of appearing mercenary if he urges his patients to come to him rather than the Health Department Clinics.

The Worcester District Society recently appointed a committee to inquire into this situation and see what could be done. This committee has secured whole-hearted cooperation from the Board of Health in urging parents to have these procedures done by their family physicians. With the cooperation of the Health Department and the City Clerk, the Medical Society is sending out a letter to the parents of every new-born child explaining to them these immunological procedures and urging them to bring the infant to the family physician for these protective measures during the first year of

life. The Society has furnished posters to every doctor for his office and to many druggists urging upon parents the importance of these measures and informing them that their physicians are prepared to administer them.

The committee feels that if the physicians would cooperate with the health authorities and overcome any reluctance they have to urge these procedures upon their patients concentrating especially on infants under one year this field of medicine could be restored to the private practitioner.

Respectfully

GARDNER N COBB, M.D. *Chairman*

36 Pleasant Street,
Worcester Mass

OFFICIAL ACTIONS OF THE BOARD OF REGISTRATION IN MEDICINE

State House Boston

July 13 1935

Editor *New England Journal of Medicine*,

This is to inform you that the Board of Registration in Medicine has restored the suspended license of Dr Eli Silverman as of July 1 1935

Yours very truly

STEPHEN RUSHMORE, M.D., *Secretary*

ELECTION OF OFFICERS OF THE BOARD OF REGISTRATION IN MEDICINE

State House Boston

July 13 1935

Editor *New England Journal of Medicine*

This is to inform you that at the annual meeting of the Board of Registration in Medicine held July 11 1935 Dr Charles P Sylvester of Boston was re-elected Chairman for the ensuing year Dr Stephen Rushmore of Boston was re-elected Secretary for the ensuing year

Dr Sylvester Dr Rushmore and Dr Edward A. Knowlton of Holyoke were designated as members of the Board to act in the Division of Chiropractic

Yours very truly

STEPHEN RUSHMORE, M.D., *Secretary*

UNEXPECTED RELIEF OF SUBDELTOID BURSITIS

July 3 1935

Editor *New England Journal of Medicine*

I hope the following experience may prove helpful to someone

A woman of middle age, while playing an active game thirteen months ago was seized with a sudden and severe pain in the right shoulder. During the ensuing ten months there was marked limitation of motion and more or less pain in the shoulder. It was difficult for the patient to do her hair and she could not raise her right hand to her back. No treatment was undertaken however

Three months ago I had occasion to give the pa-

tient a series of three antityphoid inoculations using the vaccine prepared by the Health Department of Massachusetts and employing the usual dosage of 0.5 cc 1 cc. and 1 cc at weekly intervals. The injections were followed by slight local reactions and no general reaction was noted after any of them.

The first injection was given over the left deltoid muscle and the second and third over the right deltoid. Nothing unusual was observed after the first injection but the second was followed promptly by great improvement in the mobility of the shoulder and by marked diminution of pain on motion. Further improvement of a like character followed the third injection after which mobility returned almost to normal. During the three months which have elapsed since the inoculations were completed, there has been no recurrence of symptoms and the persisting limitation of motion has been very slight.

It seems improbable that the relief of symptoms could have been brought about through psychic means because the benefit experienced was entirely unexpected. Failure of the first injection to produce any benefit and the absence of appreciable general reactions after the subsequent injections seem to exclude non-specific protein reaction as the cause. Therefore I am inclined to believe that the benefit resulted from counterirritation.

GEORGE CHESTER SEATTUCK, M.D.

The following article has been accepted for inclusion in the List of Articles and Brands Accepted

nasal deformities is more or less arbitrary, it is convenient and easily followed

For his operative procedures the author has largely followed Joseph's technique but often supplements it with modifications of his own. He rightly condemns the practice of paraffin injection for building up the dorsum of the nose yet it is regrettable that he approves of the use of ivory as a transplant for the saddle-shaped nose. This in the reviewer's opinion has no place in corrective rhinoplasty. The author's statement that general anesthesia should be absolutely interdicted and only local anesthesia used is too rigid and deserves modification.

A scholarly chapter on historical culture has been written by Dr Hermon Pomeranz and adds much to the volume as a whole.

The reviewer feels that, owing to the increased attention that has been given to corrective rhinoplasty in recent years, this compact book will be well received by those interested in this branch of surgery.

International Clinics A quarterly of illustrated clinical lectures and especially prepared original articles. Edited by Louis Hamman. Volume 1, forty-fifth series, 1935. 310 pp. Philadelphia, Montreal and London. J B Lippincott Company.

This volume is another excellent addition to a series which has achieved recognition in medical literature. There are articles helpful to the practitioner such as those on the "Management of the So-Called Blood Diseases" and the "Treatment of Diabetes Mellitus and Its Complications," and on the other hand more involved and technical are the articles on the "Red Blood Cell of Man" and "Calcium and Disease" and a review of "Cholesterol Metabolism." The authors are all competent and well known figures in medical literature.

Diseases of the Heart. John Cowan and W T Ritchie. With a chapter on The Ocular Manifestations of Arterial Disease by Arthur J Ballantyne. Third Edition, 61 pp. Baltimore. William Wood & Company \$9.00.

The rapid advances in our knowledge concerning the heart during the past decade have made it necessary for these well known British authors to revise and rewrite this book completely. This edition is therefore quite new and presents a comprehensive survey of the cardiac problems in the light of present knowledge. There are twenty-four chapters including the anatomy, physiology and pathology of the heart. The main emphasis, however, is clinical. The illustrations are sufficiently numerous and clear to add a great deal to the reader's interest. All phases of heart disease are considered, including roentgenological, polygraphic and electrocardiographic. The numerous citations and accounts of personal experiences with cases illustrate in a very readable fashion the clinical prob-

lems under consideration. This book is complete, authoritative and very well arranged. It can be regarded as one of the best volumes on the subject of heart disease that is available for the student and practitioner.

The Harvey Lectures Delivered under the Auspices of the Harvey Society of New York. 1933-1934. By Drs R. E Dyer, W Mansfield Clark, and others. Series XXIX. 262 pp. Baltimore. The Williams & Wilkins Company.

After a tribute to its late President, Dr Alfred Fabian Hess, this edition presents the Lectures of the Harvey Society of New York for the year 1933-1934. The Lectures show a wide variation in subject matter, from the purely clinical lecture of Dyer on the prevalence of Typhus and Rocky Mountain Spotted Fever in the United States, read with ease and enjoyment by the medical man, to the highly technical paper of Clarke on Potential Energies of Oxidation-Reduction Systems and their Biochemical Significance, which requires a more than speaking acquaintance with physical and biochemical laws in order to follow his discourse intelligently. Of especial interest to the medical man are the new thoughts on the rôle that inherited characteristics play in the development of intrauterine amputations, presented by Streeter in his lecture on the Significance of Morbid Processes in the Fetus, and the research work done by River on methods of propagating filtrable viruses in vitro, especially with reference to Psittacosis.

Useful Drugs A list of drugs selected to supply the demand for a less extensive materia medica with a brief discussion of their actions, uses and dosage. Prepared under the direction and supervision of the Council on Pharmacy and Chemistry of the American Medical Association. Edited by Robert A. Hatcher and Cary Eggleston. Ninth Edition. 203 pp. Chicago. American Medical Association \$6.00.

In this ninth edition of an always handy compendium the editors describe a chosen list of drugs from the enormous and increasing numbers available in the various official formularies. The average practitioner is hopelessly entangled in the mass of frequently evanescent material dealing with this phase of therapeutics. He is so bombarded by the high pressure methods of pharmaceutical manufacturers that the memory of names alone, to say nothing of physiological action and indications, is becoming an impossible burden. His only recourse is to those drugs of long tried efficiency and simple name, sensibly and briefly described in Hatcher and Eggleston's little book. The beginner should start with this *vade mecum*, and stick to it, for he will find the volume an essential part of his working library.

SECTION OF PEDIATRICS

Georgian Room, Hotel Statler Boston, June 5, 1935, 9 A.M.

PRESIDING

Dr Joseph Garland Chairman
Dr James M Baty Secretary

SYMPOSIUM ON THE CONTROL OF CERTAIN COMMUNICABLE DISEASES

CHAIRMAN GARLAND: The meeting will please come to order. One of the first duties in opening the meeting is to appoint a nominating committee to furnish names of officers for the next year. I will

appoint Dr Fred Allen of Holyoke as Chairman, Dr John Lovett Morse and Dr Elmer Barron.

It has seemed fitting to the officers of the Section this year in view of the new procedures that have been developed along epidemiological lines, to have a symposium which would help to clarify some of these rather difficult problems, and with that end in view we have I think arranged a valuable and interesting program.

The first paper on this program, which we are calling a Symposium on the Control of Certain Communicable Diseases will be a paper on measles control by Dr R. Cannon Eley of the Childrens Hospital.

THE CONTROL OF MEASLES*

BY R. CANNON ELEY, M.D.†

THE control of measles by public health measures such as placarding quarantine etc is inadequate, nor does there exist at the present time a satisfactory method for active immunization against the disease. However that measles may be either modified or prevented after an individual has been exposed by the administration of human immune antibodies has been satisfactorily established. Furthermore the advisability of either modifying or preventing the occurrence of this disease in certain individuals, and particularly among infants and children has become recognized as a warranted procedure in the practice of medicine. Therefore the problem concerned in the control of this disease resolves itself into three phases namely the epidemiological factors concerned in the transmission and dissemination of the disease the selection of the proper patients for modification or prevention, and finally the selection of a satisfactory method for the production of passive immunization. The first phase is well understood and does not warrant consideration at this time. In the following discussion

I shall confine my remarks to the consideration of the last two aspects, namely, the selection of patients for treatment and the various prophylactic measures that may be employed in the modification or prevention of this disease.

The selection of patients for modification or prevention of measles necessitates not only the consideration of the individual, but also a critical appraisal of the circumstances which resulted in the patient's exposure to the disease. In considering the patient the first question to be entertained is whether prophylactic measures should be employed to prevent or to modify the infection. The solution to this problem depends upon the physical condition of the individual, as measles and its complications should be avoided in chronically ill, debilitated, tuberculous and acutely ill children. However, if the patient is in good health and the accompanying circumstances do not contraindicate the procedure, efforts should be made to obtain modification, as complications are infrequently encountered with this form of the disease. Furthermore it is generally believed that permanent immunity may result from the modified form.

The circumstances which resulted in the exposure of the patient may, however be of such a nature as to make protection rather than modification desirable. Thus in institutions such as foundling asylums orphanages, and sanatoria it would be advisable to institute prophylactic

From the Department of Pediatrics, Harvard Medical School, the Department of Communicable Diseases, Harvard School of Public Health, and the Childrens and Infants Hospital in Boston.

Read before the Section of Pediatrics at the One Hundred and Fifty Fourth Annual Meeting of the Massachusetts Medical Society Boston June 5 1935 as part of a symposium on the control of certain communicable diseases.

*Eley R. Cannon—Associate in Pediatrics and Communicable Diseases, Harvard Medical School and Harvard School of Public Health. For record and address of author see "This Week Issue," page 240.

measures as soon after the exposure as possible in order to eradicate the disease immediately. As the immunity conferred by the usual prophylactic measures is of short duration (four to five weeks), the converse of this is true when the disease occurs in epidemic proportions outside of institutions, for in such situations modification with resultant immunity (thereby gradually terminating the epidemic) is to be sought. If this is not obtained, individuals will repeatedly be reexposed necessitating further prophylactic treatment.

At the present time passive immunization may

TABLE 1
PASSIVE IMMUNIZATION

Method	Dosage

- 2 Dosage
- 3 Time of administration
- 4 Age of patient
- 5 Degree of exposure

be obtained by the administration of convalescent serum, adult immune serum, adult immune whole blood and immune globulin obtained from human placenta. As can be seen in table 1 the effectiveness of each of these procedures depends

upon such factors as degree of antibody content, dosage, time of administration in regard to exposure, type of exposure, and the age and size of the patient. Therefore in considering the merits of each of these prophylactic measures care must be exercised that the above-named factors are duly considered.

Table 2, which has been compiled from statistics available in the literature^{1, 2, 3, 4, 5, 6}, well illustrates the influence that the above-mentioned factors may exert upon the results obtained by any of the prophylactic measures. (In order to simplify the table the age groups and time of treatment have been omitted. The ages ranged from six months to fifteen years. All patients were treated within seven days or less after exposure.) Thus it can be seen that the percentage of successful treatments obtained by convalescent serum was almost twice that obtained by the use of adult immune serum even though the dosage employed was much less. In fact, in order to obtain the same percentage of protection with adult serum as with convalescent serum, from three to four times the dosage was necessary. The marked difference between the successful protections obtained with patients treated on account of exposure in the hospital as compared with the group treated for exposure at home is not surprising for undoubtedly many of the patients considered as exposed in the hospital probably were not infected at all. This would be particularly applicable in those institutions that employ the so-called cubicle

system or where isolation technique is enforced. That an increase in the percentage of patients protected was obtained as the dosage of the serum employed was increased was to be expected as there was a proportionate increase in the antibody content. This fact illustrates the uncertainties encountered in the employment of either adult or convalescent serum when the potency is unknown. For the purpose of contrast the patients treated with immune globulins (obtained from human placental extract) were not subdivided in this table into those exposed at home and those exposed in hospitals. Instead all of the patients, regardless of the type of exposure, were grouped together, of 1341 patients treated 73.3 per cent were completely protected, 23.4 per cent had a modified form of measles and failure occurred in only 3.2 per cent. In all instances a standard dose of 5 cc was employed. The practicable value of a unit form dose does not need comment.

Table 3 demonstrates the results obtained

was less with placental extract than with convalescent serum.

One of the important questions that must be considered when any therapeutic measure is being employed is the possible untoward effects of the procedure upon the patient. Such manifestations, which usually are referred to as reactions, may be local or systemic in nature and have been noted following the institution of prophylactic therapy in measles. The fact that convalescent serum usually may be injected in adequate therapeutic amounts with only slight, if any, local or systemic reaction, has made this method superior to the employment of adult immune serum or adult immune whole blood, for when these substances are administered in amounts adequate to obtain therapeutic results, in area of tenderness, edema, and discoloration not infrequently develops at the site of the injection. Whether a systemic reaction, which usually manifests itself by malaise, indisposition, anorexia and temperature, will accompany

TABLE 3

when individuals, who were *intimately exposed*, were treated with placental extract in an effort to obtain either complete protection or modification. If these figures are compared with those of Morales and Mandry, Park and Freeman, Levinson, and Naharro and Signy (all patients received convalescent serum within five days or less after exposure and therefore should have obtained either modification or protection) it will be seen that the results obtained with the two procedures are comparable. This would indicate that placental extract is as effective as convalescent serum when employed in the prophylactic treatment of measles. This observation is further substantiated by table 4 which shows that although the percentage of patients *completely protected* was greater in the group treated with convalescent serum than with placental extract, yet the percentage of *failures*

this local reaction largely depends upon the degree of the local disturbance.

TABLE 4
PATIENTS TREATED FOR PROTECTION OR MODIFICATION
All Types of Exposure

Procedure	No Cases	Protected	Modified	Failed
Adult Serum	584	329 56.4%	139 23.8%	116 19.8%

Plac. Extract	1341	959 71.5%	321 23.9%	61 4.6%

Local and systemic reactions have been observed following the intramuscular administration of placental extract. As one might expect, these reactions occurred with greater frequency

during that period of time when the extract was first being employed and when some confusion naturally existed as to which of the various protein fractions possessed the immune bodies Table 5 illustrates this point In this table an ef-

the application of the method impracticable as a public health measure This is particularly true during an epidemic when such large quantities are instantly demanded Since it has been shown that placental extract possesses sufficient

W	6	1 16.7%	2 33.3%	5 83.3%	3 50%	0 0
	1232	729 59.2%	312 25.3%	151 12.3%	49 4%	31 2.5%

fort has been made to tabulate all of the reactions, regardless of how mild or how transient, that have been noted following the administration of the extract If the patient suffered the slightest pain or showed the slightest discoloration at the site of injection, a local reaction was recorded This type of reaction occurred in 25.3 per cent of 1232 patients, 151 patients, or 12.3 per cent, presented a febrile reaction of one degree or less, a more intense local reaction appeared in 4 per cent of the group and only thirty-one patients or 2.5 per cent showed a febrile reaction of 101° or more From these statistics it would appear that neither the frequency nor the severity of the reactions are sufficient to contraindicate the use of placental extract as a prophylactic measure in the control of a disease as serious as measles

The variability in the antibody content of adult immune serum as well as adult immune whole blood, and the fact that large amounts must be injected if satisfactory therapeutic results are to be obtained, render the application of these two substances undesirable Experience has shown that the demand for convalescent serum usually is greater than the available supply and this unfortunate condition has made

antibody content either to protect or to modify measles, and since the percentage of complete failures with this substance compares favorably with the failures encountered when other methods are employed, and in view of the fact that an adequate supply can be maintained, it would appear that the administration of immune globulins from human placenta may be the procedure of choice in the control of measles by public health measures

CHAIRMAN GARLAND I think we will reserve discussion of these papers until they have all been delivered

The next paper on the program concerns the control of pertussis, by Dr Francis C McDonald, of the Boston Floating Hospital

WHOOPIING COUGH*

With Particular Reference to Prophylaxis and Treatment With Vaccines

BY FRANCIS C McDONALD, M D †

AT a similar meeting held also on a Wednesday morning in the first week of June, nineteen years ago, Dr John Lovett Morse spoke on "Whooping Cough The Measures to be Taken for its Control and Prevention." In the

nineteen years since that time there has been some improvement in that both the medical profession and laity now seem to realize the seriousness of the disease and do not consider it a "trifling affair" which latter attitude apparently greatly disturbed Dr Morse¹

There has been a steady decline in the death rates of the four major communicable diseases of childhood, but this has been disproportionately less for whooping cough and measles as

*From the Boston Floating Hospital and the Department of Pediatrics Tufts College Medical School
Read at the Annual Meeting of the Massachusetts Medical Society Section of Pediatrics June 5 1935

†McDonald Francis C—Assistant to the Physician in Chief Boston Floating Hospital For record and address of author see "This Week's Issue" page 240

compared with scarlet fever and diphtheria and has resulted in whooping cough now assuming a greater relative importance as a factor in deaths from these infectious diseases. Between 1901 and 1930, in six countries whooping cough was responsible for a third or more of the deaths from the four infectious diseases mentioned. About ten thousand children under fifteen years of age die each year from whooping cough in this country. Roughly, six thousand die in the first year of life, three thousand from the first to the fifth year and one thousand from the fifth to the fifteenth year.²

When we consider seriously the use of a specific bacterial vaccine for increasing the resistance of the host against a specific disease process, we should feel fairly certain that the microorganism from which the vaccine is made is the cause of that disease. It is necessary then in a discussion of this type for us to review briefly certain labors on the etiology of whooping cough, particularly those relative to the major controversies.

Bordet in 1900, described tiny ovoid gram negative micrococci which were constant in their appearance and showed bipolar staining by toluidine phenol blue, and were recovered from the sputum of patients suffering from whooping cough. When other workers agreed with these observations, but on culture recovered influenza-like bacilli which were dissimilar in many ways from the organisms seen on direct observation he was stimulated to further investigation on the same subject. In 1906, together with Gengou he published a paper entitled "Le Microbe de la Coqueluche" in which they described the organism before and after culture, and suggested that the organism changed somewhat on prolonged growth. They also noted in guinea pigs the low general toxicity for a bacterial emulsion in contrast to its definite local necrotizing irritation reaction. It is also interesting to note that Bordet in this article commented upon the fact that studies of patients having this disease were less apt to be clouded by undesirable variables if observed in their own homes rather than in hospital units. In later papers he emphasized again that the organism changed its antigenic properties when grown for a long time on artificial media.³

In 1912, Mallory and Hornor described gram negative bacilli between and upon the cilia and bronchi in fatal pertussis. While attempting to prove the relationship of *B. pertussis* by further animal inoculations, it was found that in animals *Bacillus bronchisepticus*, considered by some to be the causative organism of distemper may be easily confused with *B. pertussis* (There have been rare cases of bronchisepticus infections reported in human beings with symptoms that resemble pertussis). These two organisms differ only in that the *B. bronchisepticus* is motile and grows more rapidly on some media.

They even have some agglutination phenomena in common. The antiserum of *B. bronchisepticus* will agglutinate both *B. bronchisepticus* and old strains of *B. pertussis*. On the other hand *B. pertussis* antiserum will only agglutinate *pertussis bacillus*.^{4 5 6 7 8 9 10 11}

Such discoveries called for a revaluation of all animal transmission experiments in which the disease distemper may have confused the results.

Workers again became less certain of the complexity of their knowledge of the cause of whooping cough when a series of studies on filtrable viruses indicated that some disease processes that were formerly considered to be caused by organisms of the same general family as *B. pertussis* were apparently caused by the concerted action of a filtrable virus and influenza like organisms. This is most clearly illustrated by Shope's work on Swine Influenza. Also studies on distemper, particularly those by Land and Dunkin, now seem to indicate that this is primarily a virus disease and that other organisms, including *B. bronchisepticus*, are secondary invaders. These observations were applied, mainly by McCordock, to diseases giving similar pathological pictures in man. Whooping cough, measles and epidemic influenza are frequently complicated by a type of interstitial pneumonia that can be reproduced in animals by injecting vaccine virus together with a suspension of various types of bacteria. This together with the finding of inclusion bodies in the tissues of fatal cases of whooping cough, in a relatively higher percentage than in similar control series, has led McCordock and others to suspect that whooping cough, especially when pneumonia is a complication, may be the result of a virus and *B. pertussis* complex.^{12 13 14 15 16 17 18 19 20 21 22 23}

An experiment made on four human beings by MacDonald and MacDonald is surprisingly simple, direct and convincing. A filtrate of a young culture of *B. pertussis* was instilled into the nasopharynx of all four human beings (two of whom had previously been given prophylactic inoculations of vaccine by Sauer's method) and they were quarantined for eighteen days without developing any unusual symptoms. Then a suspension containing about one hundred and forty *B. pertussis* organisms was instilled in each nasopharynx in the same manner as above. The two individuals who had not previously had vaccine prophylaxis developed definite symptoms and clinical, bacteriological and immunological signs of whooping cough. While this experiment leaves us with a feeling that whooping cough is not caused by the filtrate alone and that *B. pertussis* is the cause of the disease, contending investigators claim that it does not completely disprove the theory that it is caused by a combination of the virus and the Bordet Gengou bacilli. To settle this matter

much arises from the results in the

cently cultured organisms may carry the virus or that the virus may still have been present in the nasopharynx after the allowed eighteen day interval (see above), Shibley subcultured B pertussis organisms in their active phase over sixty times during several months. The virulent, frequently subcultured organisms produced symptoms and signs of whooping cough in the experimental animal. The author believes that frequently subculturing effectively separated these organisms from any virus that may have been present in the original culture.^{24 25}

In summarizing the known, direct evidence, the following three facts were emphasized by Miller in 1933

- 1 The close association of the Bordet-Gengou bacillus with cases of whooping cough

- 2 The absence of the organism in the cough droplets of healthy individuals who are not in contact with cases of pertussis

- 3 The great frequency with which the organism is isolated in the catarrhal stage, the time observed to be most contagious, and the subsequent diminishing frequency which parallels the observed degree of communicability.²⁶

MacDonald and MacDonald's human transmission experiments and Rich's, Sauer's and Shibley's animal transmission experiments would make a potent addition to Miller's triad.

We may conclude from this brief survey of the available evidence as concerning the etiology of whooping cough that there are no strong indications that the Bordet-Gengou bacilli are not the cause of the disease. The burden of proof lies with those claiming that a filtrable virus is responsible.

Nicolle and Connor in 1913, are usually given credit for first using a vaccine made from Bordet-Gengou bacilli on a fair-sized group of patients. They used it in a small epidemic in Tunis. Their vaccine was made from organisms recovered from the early cases for treatment of later cases in the same epidemic. In this country Graham of Philadelphia, and Maynard Ladd of Boston, reported their experiences with pertussis vaccine on a relatively few cases in 1911 and 1912. From this time on the reports were numerous and conflicting. Jones in 1928, and Lawson in 1932, submitted theses to the Harvard School of Public Health on whooping cough which carefully appraised the available evidence. Their work was carried on under the supervision of a Whooping Cough Committee appointed in 1925, consisting of Drs. George H. Bigelow, Francis X. Mahoney, Hans Zinsser, Kenneth D. Blackfan, Lawrence Smith and Richard Smith. General conclusions based on this Committee's appraisal of vaccine therapy taken largely from a series of patients studied in The Boston Floating Hospital together

with an appraisal of the literature, especially that published by members of the New York City Department of Health, are as follows:^{27 28 29 30 31 32, 33 34 35}

- 1 The homemade vaccines made from several recently acquired fresh cultures seemed to have been more effective than most stock vaccines

- 2 Therapeutic results, if any, were obtained when the vaccine was given early in the disease. Most observers agreed that after the patient had been coughing a week or more vaccines were of little avail.

- 3 Larger bacterial dosages were thought advisable.

- 4 It was agreed that heat killed vaccines were not so effective as chemically killed ones.

- 5 Prophylactic administration appeared more rational and seemed more effective than did therapeutic. However, no controlled prophylaxis by vaccine, allowing a reasonable time interval before exposure, was attempted until Madsen's and Sauer's experience.

- 6 Most all experienced workers recognized and described the difficulty of making a fair and just estimate of the therapeutic effect. In addition to the variable factors in the disease itself they recognized the unreliability of histories as given by parents. Luttinger illustrated this with the following remarks: "A case free from attacks all day long, having few paroxysms of coughing at night loud enough to awaken the father may be described as a severe case, whereas, another child with frequent severe paroxysms during the day who sleeps through the night leaves the father more indifferent. Young mothers may describe an example of coughing as unusually severe and disturbing. The same attack is trifling to the experienced matron." Histories often must be relied upon for clinical appraisal as not infrequently a really ill child may spend some time in a clinic without demonstrating the symptoms observed in the home.

Von Sholley, Blum and Smith, also of the New York City Health Department, questioned the psychological element in therapy and found that nonspecific influenza vaccine and milk-colored water were as effective as the pertussis vaccines they had been using. This same group of workers pointed out that 24.8 per cent of seven hundred non-vaccinated children who were exposed in their homes escaped the disease.

The fact that some experienced clinicians were favorably impressed by definitely good results from some vaccines and disappointing results from others together with a general realization in research laboratories that all cultures of pertussis bacteria did not behave alike prompted a series of investigations (Krumwiede, Leslie and Gaidner) which reaffirmed Bordet's orig-

inal observation that the bacillus changed its antigenic powers when cultured and recultured outside of its host particularly if grown on media free from hemoglobin.^{26 27 28 29}

Thus together with the favorable observations of clinical groups who were using vaccines on a large scale made from several recently isolated strains grown on hemoglobin enriched media (mainly in Denmark), revived the waning interest in the use of pertussis vaccines. Madsen's convincing Cutter Lecture given in Boston in 1926 describing the Danish experiences was largely responsible for renewed activity in this country.^{40 41}

At the present two vaccines are receiving the greatest attention. They are the vaccine introduced by Krueger and the vaccine introduced by Sauer.

Krueger was impressed by the work of several men which seemed to indicate the importance of the antigenic properties of intracellular constituents of bacteria and emphasized the danger of denaturation of antigenic factors by heat and chemicals. (Sauer's vaccine is killed by 5 per cent phenol.) Krueger places a bacterial suspension previously grown on media enriched with human blood in a mechanical grinder for ten to twelve hours. The ground material is taken up in buffered saline and this suspension is passed through an acetie collodion membrane which is supposed to permit the passage of a "finely dispersed phase" of the organisms and exclude "cell metabolites." A water clear filtrate is obtained, whereas, the original material was an opalescent suspension.^{42 43}

This method has raised the following questions in the minds of some bacteriologists:

If the filtrate is water-clear, is one certain that "cell metabolites" are the only masses filtered out? And after the use of these additional procedures how can one be certain of the dosage?

The clinical results following the use of this vaccine have been reported by Frawley, Stallings and Nichols, Munns and Aldrich. Their studies have been largely confined to current epidemics. Prophylactic treatment when given was within the time range of the epidemic and was not effective. Diagnoses were checked by accepted laboratory methods but the results of therapy and prophylaxis are recorded on the basis of subjective symptoms reported by patients. The results as given indicate that the disease was definitely milder and less severe in those cases receiving either prophylactic or therapeutic treatment before the end of the first week. The symptoms were relatively more severe in direct proportion to the duration of the disease before the administration of the vaccine. Reports of this sort are subject to the same difficulties of precise appraisal as were most of those between 1912 and 1928.^{44 45 46 47}

The vaccine that has excited the most interest in this country recently is that being used by Sauer. His experience in clinical and experimental pertussis extends back to 1918. He used the stock vaccines for ten years with about the same uncertain results that most of the practitioners in this community obtained. He then used a freshly prepared one of his own on one hundred cases after the onset of the disease with unsatisfactory results. From 1928 on, he apparently attacked the problem with a vengeance and seems to have humbly accepted and tried most all of the important suggestions of previous workers even to giving the study of children in their home environment a large place in his series.^{48 49 50 51 52 53 54 55 56 57 58}

His knowledge of the parents, the past histories, and the environment of the greater portion of his patients was detailed and personal as they were members of families in his own private practice in his own community. If the greater part of the study were concerned with history and symptoms as given by the parents, this knowledge used properly would tend to minimize the personal equation so far as the parents were concerned. However, a study of prophylaxis resolves itself into determining whether or not the child or the child's contacts have whooping cough rather than an evaluation of the severity of the disease.

The organism from which the vaccine is made grows best on a potato-glycerine hemoglobin media, only slightly different from that first described by Bordet. Realizing that pertussis is largely a disease of man, and recognizing the tendency of the organism to change its antigenic properties on subculture on other than a "hemoglobin" media, Sauer uses defibrinated human blood instead of defibrinated animal blood. This enables him to dispense with additional, centrifuging and washing measures which would be necessary to remove excess foreign blood protein after the bacterial harvest had been scraped off the media made with foreign blood. He thinks this also lessens the chance of immediate systemic or cutaneous reactions or of sensitization to the animal protein. The human blood is obtained from delivery rooms by collecting cord blood which is ordinarily discarded. The organisms are diluted with normal saline and killed by 5 per cent phenol.

Sauer's vaccine is diluted until 1 cc. contains approximately ten billion organisms. A total of eight cubic centimeters is generally given to each patient making a total dose of eighty billion bacteria as compared with the twenty to twenty five billion given by Madsen in Denmark and to the seven hundred million to four billion range during the 1912 and 1928 period in this country. At the present time Sauer gives the 8 cc. by three weekly subcutaneous injections (he avoids injecting in pre-

viously injected areas), 1 cc, 15 cc and 15 cc are given into each arm each respective week. The series is given during the non-epidemic period and completed at least four months before expected exposure.

His main results four months to seven years after injection as reported in an address to the New England Pediatric Society this spring were as follows:

One thousand two hundred and nine individuals were vaccinated, with sixty-two definite exposures and 152 casual exposures with six resulting cases of whooping cough. Three of the six contracted the disease shortly after recovery from measles. (This does not include an institution series of 400.)

Sauer, himself, has emphasized the need of further studies over a relatively longer period of time. As the majority of the group mentioned above have been inoculated since January of 1933 we are particularly interested in the subsequent history of his first group of 394 patients first reported upon in January 1933, which group had been inoculated during the five preceding years. Of the 394 individuals twenty-seven were from families having one or more other children, thirty-one of whom were left un inoculated as controls. All thirty-one of these controls contracted pertussis while all except one of their inoculated brothers and sisters lived with them throughout the incubation, catarrhal and paroxysmal stages without contracting the disease. Of the remainder of the original 394, 124 were reported to have been definitely exposed to the disease, yet none contracted it.

The Council on Pharmacy and Chemistry of the American Medical Association reconsidered vaccines of B. pertussis (Sauer's) in March 1934, after having previously omitted them from New and Nonofficial Remedies in 1931. They granted that Sauer's work appeared promising, but before rerecognition of the value of pertussis vaccine expressed a desire that a larger series of cases be collected and that they be gathered from a less localized geographical area.¹⁰

The Michigan Board of Health and the commercial laboratories are now manufacturing vaccines following Sauer's method. However, in making them on a large scale they find it difficult to collect human blood in sufficient quantities for use in the potato-glycerine media. Hence, animal blood is being used in the preparation of these vaccines. Kendrick, representing the Michigan State Board of Health, sees no reason why animal blood should not be used. Sauer still feels that until the value of the vaccine has been proved more definitely the technique of manufacture should not be altered. At the present time he does not use his vaccine for other than prophylaxis. This is in agreement with past clinical experience and with the

general feeling of many bacteriologists that the development of immunity as stimulated by vaccines is a matter of several weeks rather than of a few days.

In conclusion, while we cannot ignore the possibility that a filtrable virus may play a part in the disease picture, the proponents of vaccine prophylaxis have offered a program that gives promise of preventing whooping cough in the young patient. A question that naturally arises is: Are there any serious contraindications to the use of the vaccine? Two deaths are reported in Madsen's series in infants vaccinated because there was whooping cough in the immediate family. One was newly born. Four days after an inoculation of 1 cc, a second of 15 cc was given, thirty minutes later the patient died with hiccoughs, cyanosis and contracture of the extremities. The second fatality occurred in an eight day old premature infant. The first inoculation was 1 cc, the second 2 cc after a three day interval. Two hours later death occurred suddenly with slight cyanosis.

These deaths, particularly the latter, occurred in an uncertain age period where the vaccine may have played no direct part in the fatalities. However, the use of the vaccine made from organisms grown on media enriched with human blood prepared as advocated by Sauer appears reasonably safe and rational if given after the seventh month of life with the series completed at least four months before exposure. Sauer does not think that immunization should be attempted very soon after recovery from other diseases (N.B. measles) or within several months of other immunization (Diphtheria, smallpox, scarlet fever).

The Bordet-Gengou bacillus does play an important rôle in the disease picture of whooping cough. While vaccine therapy appears to be of doubtful value, vaccine prophylaxis as outlined by Sauer offers definite promise. However, several years of further use will be necessary for final evaluation.

CHAIRMAN GARLAND The third paper on the program will be on scarlet fever by Dr. Gaylord W. Anderson Director of the Division of Communicable Diseases of the State Department of Public Health

THE PRESENT STATUS OF SCARLET FEVER PREVENTION*

BY GAYLORD W. ANDERSON, M.D.†

TWELVE years have now elapsed since the Dicks announced their basic scarlet fever studies showing the etiologic relationship of certain hemolytic streptococci* to the production of a toxin injection of which might be used in small quantities to determine susceptibility* and in large doses to enhance the human resistance* and the production of a specific antitoxin which might be used for the treatment of the disease*. The ensuing years have seen a large number of subsequent studies and the presentation

of much material the exact interpretation of which is far from clear, yet so far as I am aware, none of it has upset any of the fundamental facts originally established.

In attempting at this time to bring before you a brief critical analysis of the present status of scarlet fever prevention, it seems best that the conclusions should be based solely upon the findings of other observers than the Dicks and their immediate associates*. My decision to do so was based primarily on the thought that the true practical value of such methods lies not in the results claimed by those originators who may have acquired special skill in a certain technique and who because of a pardonable pride in achievement may unwittingly view all doubtful data in their best possible light but

*From the Massachusetts Department of Public Health. Read before the Section of Pediatrics at the One Hundred and Fifty-Fourth Annual Meeting of the Massachusetts Medical Society, Boston, Dec. 1924, as part of a symposium on the control of certain communicable diseases.

†Anderson, Gaylord W.—Deputy Commissioner and Director of the Division of Communicable Diseases, Massachusetts Department of Public Health. For record and address of author see "This Week a Issue," page 216.

rather in the results obtained by others less familiar with the technique and approaching the problem without the least element of possible prejudice. They who come to criticize but remain to applaud are the best supporters of any cause. I have further thought it better to omit the results claimed by the Dicks because unfortunately many of the articles are so lacking in the details essential for a critical analysis as to leave doubt as to the exact value of the figures. This doubt is enhanced by claims which, if substantiated, would place the Dick test and the immunizing toxin in a separate class by itself, far superior in reliability and value to any other known biologic agents, a rating that cannot be accorded to them by the findings of other observers no matter how favorable their results. It has, therefore, appeared wise to base our opinions solely on the work of investigators other than those associated with the Scarlet Fever Committee.

THE DICK TEST

The first problem that must be considered is the reliability of the Dick test as an index of immunity to scarlet fever. To what extent can it be said that a person with a negative Dick test is immune to the disease? Studies of hospital nurses and internes, the majority of whom are at one time or another exposed to scarlet fever, furnish probably the most severe test. Thus Knights²⁴ on the basis of a one year's experience with a small group in Providence reports an attack rate of 2.1 per cent among the Dick negative nurses as contrasted with a rate of 18 per cent for the Dick positive. Peacock, Werner and Colwell²⁵ in Chicago report only one questionable case of scarlet fever among 186 nurses with a negative test, and two out of five whose test was positive. Faulds²⁶, at the Royal Infirmary in Glasgow, found no cases among 298 Dick negative nurses for a three year period. Boynton²⁷, studying the nurses in the University of Minnesota School of Nursing, found one case among 376 negative reactors, whereas seven of 619 that were neither tested nor immunized contracted the disease. Toyoda²⁸ and his associates working in Japan, found no cases among 157 immune hospital attendants and ten cases in forty-three susceptibles. In Edinburgh, Benson and Rankin²⁹ report but five cases among 1,063 negative reactors intimately exposed to the disease and fifty-two cases among 363 Dick positives who were in general less intimately exposed. In a survey of the hospitals in Massachusetts, Anderson and Reinhardt³⁰ found for a period ranging from one to eight years only nine cases of scarlet fever in 1,337 nurses with a negative reaction, whereas thirty out of 234 (12.8 per cent) of those who had a positive test and were not immunized contracted the disease.

These results from a group whose exposure to scarlet fever has been unusually intimate indi-

cate a high degree of specificity for the Dick test. The results are substantiated by institutional and community studies. Probably the largest series is that of Sparrow³¹ who tested 23,657 children in Warsaw during 1925 to 1927, of whom forty-five per cent, were Dick negative. During the ensuing winter, when scarlet fever was at a high level, there were but four cases

TABLE 1
RELIABILITY OF DICK TEST
AMONG NURSES

Observer	Dick Neg	Cases of S F	Rate	Dick Pos	Cases of S F	Rate
Knights	143	3	2.1	22	4	18%
Peacock, etc	186	1	0.5	5	2	40%
Faulds	298	0	0	—	—	—
Boynton	376	1	0.3	—	—	—
Toyoda et al	157	0	0	43	10	23%
Benson and Rankin	1063	5	0.5	363	52	14%
Anderson and Reinhardt	1337	9	0.7	234	30	13%
	3560	19	0.5	667	98	15%

in this immune group as contrasted with 127 in the susceptible group. Nesbit³² has found comparable data in the school system of Gary, Indiana, one year's observation showing no cases of scarlet fever in a group of approximately 1,000 spontaneously immune children. Albescio³³ reported an attack rate of 0.2 per cent among 3,051 Dick negative Roumanian children, as compared with 4.6 per cent among an unimmunized Dick positive group. Kiefer³⁴, Molitch³⁵ and others have reported comparable results in institutions. In Japan, however, Toyoda and his associates²⁸ found forty-eight cases among 7,186 Dick negative school children, an attack rate of 0.7 per cent, as contrasted with 209 cases (4.4 per cent) in a group of 4,733 susceptibles. They³⁶ quote the experience of Ozaki, likewise in Japan, who found an attack rate of 10.6 in a small susceptible group as contrasted with a rate of 0.1 in a Dick negative group of 1495 children. Similarly, in a group of home contacts, Toyoda²⁸ reported no cases among seventy-three immunes and six, or 11.5 per cent, among fifty-two susceptibles. More recently Gordon and his associates³⁷, working in Detroit, found in a study of family contacts an attack rate of two per cent among 723 Dick negatives, as contrasted with thirteen per cent among 566 susceptibles.

These results have been selected as typical examples of the findings of investigators in many different places. While they differ slightly in the exact degree of immunity indicated by a negative Dick test, they all agree, however, in indicating that the Dick test is in practice an extremely sensitive measure of resistance to clinically recognizable scarlet fever. It is true that

failures of the test will be encountered, but in this respect it differs in no regard from the Schick test. As a measure of human resistance to the disease it is therefore an extremely valuable and reasonably reliable addition to our control procedures.

PASSIVE IMMUNIZATION

Passive immunization is possible through the use of three different products. Antitoxin originally recommended by the Dicks, will unquestionably give a protection lasting from two to four weeks. It has, however, fallen into more or less disrepute because of the subsequent serum reactions which are frequently more severe than the prevailing type of scarlet fever. There is, however, no doubt as to its efficacy. Blood serum from those convalescent from the disease may likewise be used where obtainable. Here also there is little doubt as to its efficacy if used in sufficient quantities, though the optimum dosage for different patients has not been determined. Meader²³ reported an eighty per cent reduction of secondary cases through a

dosage of 75 cc, though Gordon²⁰ finds larger doses preferable. The principal problem here, however, is that of obtaining enough serum for the needs of a community. More recently McKhann²⁰ has demonstrated a similar protective action from an extract of the placenta. All of these methods confer, however, merely a temporary protection and are of no lasting value.

ACTIVE IMMUNIZATION

Evaluation of the results obtained through active immunization using graduated doses of the Dick toxin is extremely difficult because of variations encountered in the dosages used. The early work of the Dicks and others must be largely disregarded because the dosages used were so small as compared with the present-day schedule that the results are not comparable. Yet in spite of the improvements coming from larger doses, one cannot help wondering if the advantage of improved level of protection may not have been outweighed by the obvious disadvantages of reactions and number of injections.

The protection obtained from these injections can be measured either in terms of their effect on the Dick test or the protection conferred to subsequent exposure to the disease. It can be generally stated on the experience of many different observers that the present-day dosages of 500, 2,000, 8,000, 25,000 and 80,000 skin test doses (S.T.D.) will cause a positive Dick test to become negative in about 90-95 per cent of the persons so treated. With smaller doses the percentage will fall off though by no means proportionately to the decrease in units.

The clinical evidence as to the immunity so established is best measured in the groups of hospital attendants. In table 4 are summarized many of the data now available. Although there was some variation in the doses of toxin used, the total number of units rarely fell below a total of 80,000. The difference between the low attack rate of 0.5 for the immunized nurses and fourteen per cent for the known susceptibles permits of no other interpretation than that the toxin injections have in reality conferred a high level of protection.

TABLE 4
TOXIN IMMUNIZATION
SCARLET FEVER ATTACK RATE AMONG NURSES

Observer	Immunized			Dick Cases Rate			No Test	Cases	Rate
	Pos	Cases	Rate	Pos	Cases	Rate

	1850	7	0.5%	667	98	15%	5295	187	3.5%

Includes some children as well as nurses.

Similar data are available for community studies. Thus Nesbit and Thompson⁴² report that in the Garv schools there have been approximately 10,000 given the toxin and during eight years only nine cases of scarlet fever among those who were negative on the retest Sparrow⁴¹, using dosages of but 3,500 STD found a reduction to one-fourth of that in the non-immunized group. Albescio⁴³ in Roumania, using small doses, never exceeding a total of 13,500 STD of toxin, found in two years an attack rate of 1.2 per cent among the immunized as compared with 4.6 per cent among a much smaller group of non-immunized susceptible children. Tovoda and his associates⁴⁴, using dosages of 25,000 to 40,000 STD, found an attack rate in Dairen of but 0.1 per cent among the immunized as contrasted with 6.2 per cent among the non-immunized. They also quote the experience of Ozaki, who found a rate of 0.3 per cent among the immunized and 2.4 per cent among the non-immunized. To these series might be added the experience of numerous institutions in this country and abroad showing that in the face of an outbreak those immunized with the Dick toxin were protected, although new admissions that were not so protected contracted the disease. It is therefore a fair statement to say that immunization with the Dick toxin in adequate doses confers to a person previously susceptible a level of resistance against clinically recognizable scarlet fever that is comparable to that shown by a negative Dick test, and furthermore, that this protection is probably comparable in effectiveness to that conferred against diphtheria through the use of the commonly accepted immunizing agents.

DURATION OF IMMUNITY

The exact measure of the duration of immunity is hard to determine because it usually is impossible to measure the extent to which the rapidly developed immunity produced by the toxin may have been maintained or enhanced by subsequent exposures to new infecting doses of the causative organisms. The results among nurses would suggest an immunity of at least three years though in this group especially there is, theoretically at least, opportunity for much reinforcement of the resistance through frequent exposures to subinfecting doses. Nesbit and Thompson⁴² report eighty-one per cent immunity by Dick test among 171 children immunized five or more years previously while Bull⁴⁵ found sixty-four per cent negative and thirty-six per cent slightly positive among fifty immunized eight years previously. There are few published data available as to the permanence of a negative reaction among those found naturally immune. In studies carried on by the Department we have found in an institution where scarlet fever was not

prevalent that 644 or eighty-nine per cent of a group of 725 originally negative were still Dick negative four years later, a finding that compares quite favorably with similar studies of the permanence of a negative Schick test in a similar institution under similar conditions. On the other hand, of forty-one susceptible children left unimmunized in the same institution, thirty-one or seventy-five per cent were still susceptible at the end of four years.

REACTIONS

Whatever may be the differences of opinion as to the reliability of the Dick test and effectiveness of immunization with Dick toxin, there is a surprising unanimity of opinion as to the severity of the reactions encountered from the toxin injections. These reactions may be briefly described as nausea, vomiting, headache, fever, rarely sore throat and occasionally a typical scarlatiniform rash with or without desquamation. Most observers mention "severe" reactions in as high as ten to fifteen per cent of those so treated. These reactions have been sufficiently severe so that they have unquestionably militated against the ready acceptance of scarlet fever immunization in many instances. Thus many nurses have preferred to take their chances with the present mild form of the disease. In community programs there has been a markedly greater falling off in clinic attendance⁴⁶ than is encountered in similar diphtheria immunization programs. Melnick⁴⁷, in institution work, was even prompted to recommend a "pre-immunization" preparation of a laxative, diet restricted to fruit juices, cereal, water, tea and toast on the day of the injection, restricted activities, and injection given at night and just before a week-end so as to avoid absence from school of those who would be in bed the following day. This latter is probably an extreme point of view, but the fact is inescapable that a definite percentage of those who are so treated will probably require bed care during the ensuing twenty-four to forty-eight hours. Unfortunately, it does not seem possible to avoid these reactions by reducing the dosage, as they have been described following doses that are but a fraction of that recommended by the Scarlet Fever Committee as needed for a lasting immunity. It is necessary, therefore, to turn to other types of preparations in search of immunizing agents that can be given without unpleasant reactions.

"TOXOID" IMMUNIZATION

Since the early days of toxin immunization many attempts have been made to modify the toxin in a manner comparable to that used in the preparation of diphtheria toxoid, in the hope of obtaining a potent immunizing agent that would at the same time be devoid of the

severe toxin reactions. Many preliminary but inconclusive reports have been published in this country and abroad, leaving the question still very much open to debate.

The most recent attempt in this country to produce a scarlet fever toxoid has been that of Veldee, who in 1930¹⁶ and 1931¹⁷ reported preliminary studies to this end, and in 1933¹⁸ reported its use on several hundred children. Some of this work was carried on in collaboration with the Massachusetts Department of Public Health. Beginning with these studies in the fall of 1931 and continuing through the present day, the Department has been pursuing extensive studies of this formalized toxin solution prepared according to the methods of Veldee.¹⁸ In the course of the studies we have Dick tested over 15,000 children and administered the material to 6,000 to 7,000 children. These studies have been carried on in twenty-seven different institutions. In the nurses' training schools of several hospitals and more recently on a community wide basis in ten cities and towns. In some of these institutions the studies have been under way for about four years and in the majority for over two years. In two of the communities, over a year has now elapsed since the immunization work was completed and we are beginning to obtain results of real value. The work in the other communities has been concluded during the past winter or is at the present moment being finished so that no conclusions will be available for at least another year.

I am not prepared at the present moment to report to you in detail as to the results of these studies, other than in generalities. The material is being given in but three injections three weeks apart. The reactions it produces are no more severe than are encountered in diphtheria immunization and markedly less severe than with the Dick toxin. This is attested to not only by the physicians, superintendents, nurses and teachers who have seen its use, but also by the parents who have brought their children back for subsequent injections equally readily as for diphtheria. As measured by the Dick test the resulting immunity is not so high as obtained through the five doses of toxin, as recommended by the Dicks. Work of the past winter has strongly suggested, however, that after "toxoid" immunization, control tests with a heated toxin are essential to eliminate false positive reactions. These may give to the retests a more flattering appearance. The value of the "toxoid" when measured by the clinical test of protecting against clinically recognizable scarlet fever has been strikingly shown in a virtual absence of the disease from the institutions where it has been used. In the two communities where

it has been possible to evaluate results, there has been demonstrated a marked degree of protection for those children given the "toxoid." Clinically, therefore, it is fair to say that at present it appears to offer an immunizing agent that, through its ready acceptance because of mild reactions, may be used so extensively as to lessen materially the incidence of scarlet fever even though the protection conferred in an individual case may be less than with the more powerful Dick toxin.

"SCARLATINAL TONSILLITIS"

In the midst of the studies of scarlet fever immunization the suggestion has frequently been advanced that immunization by protecting the individual against the rash would be followed by an increase in sore throats of streptococcal origin, which would in reality be scarlet fever without a rash or, as Benson has named them "scarlatinal tonsillitis". Kinloch, Smith and Taylor¹⁹, on the basis of a single year's experience, reported an increase in cases of tonsillitis among nurses after immunization has been carried on. Gordon and his associates²¹ in a study of family contacts with cases of scarlet fever found that ten per cent of the Dick positives developed tonsillitis without rash whereas but 4.5 per cent of the Dick negatives had a similar experience, a rather surprising difference were the Dick test to indicate merely a resistance to the toxin and not to the infection itself. Benson and Rankin²² in their studies at the City Fever Hospital of Edinburgh found no increase in tonsillitis among the probationer staff the preimmunization attack rate 1919-1925 being 22.1 as compared with a rate of 16.5 for the years 1926-1933 after immunization had become a routine. They have further studied the cross infection rate of scarlet fever to diphtheria patients as a test of the hypothesis that immunized nurses might more readily be carriers of the hemolytic streptococci of scarlet fever. Their results showed that during the preimmunization period 3.5 per cent of the diphtheria patients contracted scarlet fever, whereas during the years subsequent to the inauguration of scarlet fever immunization among the nursing staff only 2.1 per cent developed a cross infection of scarlet fever. They conclude that "there is no evidence that clinical scarlet fever has been replaced by 'scarlatinal tonsillitis' in successfully immunized nurses and an immunized nursing staff does not increase the risk of conveyance of scarlet fever to non-scarlatinal patients." I know of no evidence that would prove the incorrectness of this statement.

SUMMARY

In summarizing this analysis of the present status of scarlet fever immunization I hope I may be pardoned if I express a personal estimate as to the value of the data here presented. Many of us, and I include myself among the group

¹⁸Recently the Dicks¹⁸ have questioned the existence of a true toxoid, maintaining that the immunizing effect of the solution is due solely to the residual toxin that has been unaffected by the formalin. Further studies are needed to clarify this situation.

have been so impressed with the reactions encountered from Dick toxin immunization that we have hesitated to recommend its use. This would be justifiable were it not for the fact that we have rationalized our hesitancy upon a doubt as to the validity of the Dick test and the efficacy of the toxin. The issues are in reality quite separate, but we have permitted them to become confused in our minds. We must, I believe, recognize that the Dick test is in reality a very reliable index of immunity to scarlet fever, little if any inferior to the Schick test in its own field. We should also acknowledge that with the Dick toxin susceptible persons can actually be protected against scarlet fever with a measure of success little short of that seen in diphtheria. Its only limitations are the reactions encountered which will probably for a long time to come make its use impractical on a community basis in public clinics. In institutions, and in the hands of the private practitioner, on the other hand, who can explain in advance the possibility of reactions and thus avoid alarm on the part of the parent, it offers an extremely effective means of scarlet fever control and is deserving of more extensive use than at present accorded to it.

CHAIRMAN GARLAND The next paper on the program is on diphtheria, by Dr Elliott S Robinson, Director of the State Antitoxin and Vaccine Laboratory

THE CONTROL OF DIPHTHERIA*

BY ELLIOTT S ROBINSON, M D †

THE experience of the last twenty years, more particularly the last ten, has shown clearly that the most satisfactory method of controlling diphtheria consists in active immunization of as many children as possible. There is every reason to believe that the more thoroughly and completely this practice is carried out, the lower will be the incidence of the disease in the community. Therefore, the discussion of the control of this disease consists not in considering whether active immunization should or should not be carried out but upon what immunizing agent should be used for that purpose.

The first immunizing agent to be used on a large scale was diphtheria toxin-antitoxin mixture. Dr Theobald Smith's suggestion made in 1907 that a mixture of toxin and antitoxin might be useful for human immunization was

first employed by Dr William H Park in 1913. In the twenty-two years since that time many thousands of children have been immunized with mixtures of this sort. Our experience in Massachusetts has shown that toxin-antitoxin mixture is efficient, safe and in a great many ways entirely satisfactory. It is true that in two communities there were severe reactions following the use of material which had been frozen, but that material was made by a formula now no longer in use and there is no reason to believe mixtures of the present type are subject to increased toxicity when frozen. On the other hand, frozen mixtures may prove to be less satisfactory as immunizing agents and should, therefore, never be used.

Chiefly as a result of some case reports from the middle west, there has been created a fear that toxin-antitoxin mixture will sensitize to horse serum. We have not felt that the sensitization so resulting, if it occurred at all, was of a degree to be practically important. The continued use of toxin-antitoxin mixture during the past two years when diphtheria toxoid has been

*From the Massachusetts Department of Public Health. Read before the Section of Pediatrics at the One Hundred and Fifty-Fourth Annual Meeting of the Massachusetts Medical Society Boston June 5 1935 as part of a symposium on the control of certain communicable diseases.

†Robinson Elliott S—Director Division of Biologic Laboratories Massachusetts Department of Public Health. For record and address of author see "This Week's Issue" page 240.

available also shows that this fear is not generally held by the physicians in Massachusetts. For reasons which will be gone into later, our present feeling is that diphtheria toxin-antitoxin mixture remains the most satisfactory immunizing agent for use in adults and in older children, but may well be replaced by diphtheria toxoid in younger children.

About ten years ago Ramon in France introduced the use of diphtheria toxoid or as he called it "anatoxine." This material consists of diphtheria toxin which has been detoxified by the addition of formalin and a period of incubation lasting a month or more. As a result of this treatment, the toxin loses entirely its poisonous properties but retains those properties which give it antigenic value. Extensive experience abroad, particularly in France, but also in Canada and many parts of the United States, has shown that diphtheria toxoid is a satisfactory immunizing agent. The chief objection to its use lies in the fact that older children and adults may have reactions, both local and general, following its use. These reactions are probably due to previous sensitization to the protein of the diphtheria bacillus, and inasmuch as opportunities for sensitization are more numerous the longer one lives, such sensitization is, therefore, more likely to be found in older individuals. When we first distributed this product in Massachusetts, we recommended that it be used only in children under the age of six. Since then we have gradually raised the age limit until now we feel that it may be used with safety in children certainly up to the age of eight or ten and possibly somewhat older. There is some reason to believe that the age limit may be higher in those communities that have had relatively little diphtheria, and that the age limit should be lower in those communities having a good deal of diphtheria. Although we have no figures to support such a statement, it is quite in line with what we know of the disease and of immunization to it. In beginning immunization in a community with diphtheria toxoid, the most logical procedure would be to start with the younger children and as they were done with no reaction gradually increase the ages of the children immunized until reactions became too frequent to be satisfactory. Inasmuch as the reactions are unpleasant or uncomfortable rather than dangerous there would be no harm in such a procedure and it would lead to the immunization of the greatest number of children with diphtheria toxoid rather than with diphtheria toxin antitoxin mixture. For those children in the higher age groups, toxin antitoxin mixture should be used.

The number of doses and the intervals between them have been the subject of much discussion. This question is best answered by recalling that the five important factors in producing immunity are the antigen, the size of the dose, the number of doses, the interval between doses and

the basic immunity of the individual, and that we are anxious to produce the highest level of immunity reasonably attainable. We have advocated three doses rather than two because three doses are necessary to attain high levels of antitoxin. The interval of three weeks between doses probably does not give a much larger percentage of Schick negatives than are obtained with intervals of a week, but each individual will have more antitoxin and, therefore, will remain Schick negative longer, because it takes longer for the antitoxin content to fall from the higher value. If only two doses of toxoid are given, the interval should be not less than a month.

Within the past few years there has been a great deal said about alum precipitated diphtheria toxoid. This product consists of the diphtheria toxoid previously described which has been treated by the addition of alum to give a precipitate. After washing this precipitate is resuspended in salt solution. The dose is usually 0.5 or 1 cc. The advantage claimed for the use of alum precipitated toxoid is that only one injection is required and that the level of immunity obtained is at least as high as is ordinarily obtainable with three doses of diphtheria toxoid. The early reports of immunization with alum precipitated diphtheria toxoid, particularly those from Alabama, indicated that very satisfactory results were secured. Following the experience in Alabama other manufacturers undertook to produce this product and it has been used rather extensively during the past few years. In many instances the results obtained have been quite in line with the original claims but in other instances results have not been so satisfactory. Unfortunately, certain lots of alum precipitated diphtheria toxoid have given rise to local reactions which have gone on to the formation of sterile abscesses. In some instances these abscesses have occurred in a large proportion of children inoculated. So far as I know, none of these reactions have left any important sequelae, but such occurrences tend to give a bad reputation to the process of immunization. It is thought that these severe reactions may be traced to one of two causes, both of which lie in the method of manufacture. Some lots which have caused reactions have had a high content of alum. In other instances the fault has been laid to the fact that the toxin was allowed to incubate for a rather long period during the process of toxin formation. This caused the autolysis of an unduly large number of diphtheria bacilli and consequently a high content of diphtheria bacillus protein. One or both of these factors have been involved in those lots which have given unduly numerous reactions, and it is felt that, by avoiding these two faults, reactions may be prevented. A third source of reactions lies in the same mechanism which gives rise to reactions with the ordinary diphtheria toxoid, namely that the in

nothing to what he has said except to call attention to further experimentation which is being carried on to determine the efficacy of placental extract given by routes other than subcutaneous injection. The practical matter which we have to decide is whether to use any substance and if it is to be used, when. Except under unusual individual circumstances, modification of the disease is preferable to protection. Modification should be used for all exposed children who are under three years of age and probably for all under five years of age. If further experience proves that subcutaneous inoculations can be displaced by a method of administration which gives no reaction, it would seem desirable to modify the severity of the disease in all persons exposed to measles.

4 In the fourth group, procedures of possible efficacy but still in the experimental period, we would place immunization against whooping cough. Perhaps one should mention poliomyelitis also, but fortunately it is outside of the field under consideration this morning.

Pertussis is such a dread disease that physicians and parents easily take "the will for the deed" so far as proof in relation to prevention is concerned. Dr. McDonald has been judicial in his conclusions. All of us would do well to follow his lead. Enthusiasm in relation to the value of vaccines has waxed and waned many times. Just now we are in a period of optimism but there have been times in the past when success seemed almost as near at hand as it does to-day and further experience has ushered in a period of depression. One is certainly justified in using vaccine in an attempt to produce immunity against whooping cough but one must be honest with himself and with his patients in acknowledging that proof of its protective efficacy is lacking. One must also guard against drawing conclusions from a few cases, from clinical impressions or from uncontrolled statistical reports. Time will determine whether a vaccine can be prepared of such a quality that, administered according to a given technique, it will afford protection against the disease. Until then let us maintain an open mind.

CHAIRMAN GARLAND I will now ask for the report of the Nominating Committee.

DR. ALLEN The Nominating Committee submits the following report:

Chairman for next year, Dr. George P. Hunt, of Pittsfield, and for Secretary, Dr. James M. Baty of Boston.

CHAIRMAN GARLAND You have heard the report of the Nominating Committee for Chairman, Dr. George P. Hunt, for Secretary, Dr. James M. Baty. Are there any further nominations? If not, the Chair will entertain a motion for the nominations to close.

[Voted, that nominations be closed.]

CHAIRMAN GARLAND The Chair will entertain a motion for the Secretary to cast one ballot for these officers.

[VOTED, that the Secretary cast one ballot for the officers as nominated.]

The Secretary cast one ballot for the officers nominated, and they were declared duly elected.

CHAIRMAN GARLAND The papers are open for discussion. I will ask the discussers to give their names and addresses plainly, and remember that discussion is limited to two minutes.

DR. CONRAD WESSELHOEFT, Boston In regard to the use of convalescent serum in measles, I would like to say a word from the standpoint of one who holds the pursestrings of one supply of this convalescent measles serum. It is not a pleasant position to hold because some people have the idea that measles is such a dread disease that it is very dangerous, even for an adult, and some family physicians explain to their adult patients that in the event of exposure and no knowledge of having had measles, if they could get some of this convalescent measles serum they would not come down with measles. Of course, the breadwinner of the family does not want to contract the disease, and pressure is brought to bear on some of us who hold the pursestrings of this convalescent measles serum. If he happens to be a hospital trustee then I am up against it. I would like to say that it takes at least four times as much of this very valuable convalescent measles serum to protect a full grown trustee as it does to protect a small child. The difficulty in obtaining the serum lies in the fact that it is obtained only from adults, and few adults have measles.

I would like to emphasize the ruling that has been made in Providence, where they do not release the convalescent measles serum for any case that is not under four years old, except under those conditions which Dr. Eley brought out, for instance, if a child has whooping cough or is convalescent from scarlet fever. Then, of course, it is very desirable that the measles serum should be used.

I think the general tone to day has been to stress the severity of these diseases. I think it is overstressed. The high mortality in measles comes before the age of four. After that it is not, according to the statistics, a dread disease. So I welcome, and so does everybody welcome, a placental extract which is so effective, and which may do away with this demand for convalescent serum which is far greater than the supply. At contagious hospitals a supply of this convalescent measles serum has to be kept on hand because measles can very well break out in a scarlet fever ward.

I would like to say in connection with this that I am always very much surprised when a doctor sends to the Haynes Memorial a case of scarlet fever knowing perfectly well that that child has also been exposed to measles within a week, and yet says nothing whatever about it at the time he calls up to admit the case. It is astonishing how often that happens.

As to scarlet fever, we must all welcome this toxoid because we know that we do get unpleasant results from the use of the toxin in the usual doses, or even though we split them up, as I do, into eight doses over eight weeks, and even then we sometimes get reactions. The toxoid would seem to do away with that.

Just one more point here, and that is that those of us who are interested in scarlet fever are very much concerned about this Dick patent. Of course, the discovery of the toxin was an important step, as has been brought out by Dr. Anderson. The active immunity obtained from this toxin not only protects against the disease but it protects against the complications as well, because pupil nurses so protected by inoculations when intimately exposed on scarlet fever wards not only fail to come down

with scarlet fever but they also do not come down with tonsillitis otitis media and all the other complications arising from the pyogenic property of this hemolytic streptococcus. On the other hand the patient in the early stage of scarlet fever who is given the antitoxin may be immediately and dramatically benefited for the time being but is not thereby protected from the subsequent complications. Our present conception of the origin and nature of all these complications is very unsatisfactory.

The trouble with the Dick patent is that it not only covers the discovery of the toxin but all the discoveries which lead up to it and furthermore the patent is so all-embracing as to prohibit anyone from inoculating with any scarlet fever toxin any human being or animal who is not licensed by the Scarlet Fever Commission in Chicago. The patent was sanctioned by a committee of the A.M.A. with the idea that it would protect the profession from bad products during the period of its introduction. That was ten years ago. Such protection is no longer needed. It indeed it ever was needed. The Massachusetts Medical Society in Council yesterday passed a resolution that this Society was opposed to the continuation of that patent and the delegates were to bring that resolution before the American Medical Association.

CHAIRMAN GARLAND Is there any other discussion?

DR. H. B. MARBLE, Shelburne Falls I have just three questions I would like to ask. The first one is: What is the present status of the value of ether injection in the treatment of whooping cough? The second: What would be a suggested dose or average dose of toxoid in pupils of high school age? The third one is: We all know there are many children in the high schools who have been vaccinated but not successfully. What can be done about getting these children vaccinated so that they will be immune to smallpox?

CHAIRMAN GARLAND Any further questions?

DR. EDWARD M. SMITH, Salem, New Hampshire I wish to call attention to the importance of the mammalian transition period after birth and at the commencement of nursing. I believe that some of our pediatric problems along the line of discussion begin here. They can be solved or dismissed without understanding by the use of the neglected substance the placenta.

The physiological effects and biological substances in the after-birth are too challenging for further neglect. (1) The fascinating McKhann immune bodies have been discussed and they or their precursors may be transmitted from the milk of the placenta-fed or placenta-extract-enriched post-partum woman. (2) Not common knowledge is the fact that placenta has been shown to be one half more valuable per weight than the best liver in blood remitting substance or what I shall call Carnivorous Substance X (verbal communication, Dr. William Castle, 1936). (3) Estrogenic substance is present in highest titre in this embryonal material. It has definite lactogenic effects even on the male and one of the best tests for its presence is the growth of nipple and areolar skin. It may cornify and change the whole mucosa of the genital tract within forty-eight hours. It has been used to secure resistance to juvenile gonorrhea. It should be carefully tried in attempts to render the postpartum state more promptly non-invasive. (4) The hemorrhagic diseases of the newborn with an incidence of 16 per thousand may possibly be dismissed by placenta extract directly or through the mother. This ery-

throblastic crisis responds to liver extract and the naturally available substance should be preferred. Its explosive potentiality in stimulating and homeostatic balancing of mitosis is well known by the typical Minat-Murphy reticulocyte curves. (5) The presence in high titre of progestin requires observation of the control over involution and subinvolution of the uterus. (6) The nonspecific substances present in both liver extract, placenta, and placental extract which extends to cord and brain changes in primary anemia may reasonably be expected to disturb postnatal nutrition and render breast feeding more vitally valuable. The effect needs study in the jaundice of the newborn, the immunity of the newborn, the early and later mortality of the newborn. It certainly may be used in the primary anemia of pregnancy.

Lying in hospitals as my own the Boston Lying In are to date disposing of as garbage this most valuable physiological material. It should be saved, extracted and rendered generally available for the studies indicated. About 3000 lbs. is lost in this hospital alone.

Mammalian survival has been largely conditioned by the conservation of all already elaborated material. Placental eating and the resorption of the young are common indicators of nature's extreme conservatism in a mammalian economy. The discovery of carnivorous substance X (blood important) is partly based on the observation of carnivorous conservation of most valuable elaborated substance.

Important questions are suggested by my remarks with respect to correction of past errors in the treatment of the newborn child and the mother.

CHAIRMAN GARLAND Any further discussion? Dr. Eley have you anything to add?

DR. ELEY No.

CHAIRMAN GARLAND Dr. McDonald? Perhaps you can answer this question as to the use of ether and oil.

DR. McDONALD Dr. Smith perhaps could give a more complete answer to the question concerning the use of ether injection in the treatment of whooping cough. I have had no experience with its use. Local practitioners seem to agree that the average case of whooping cough will respond best to rest and that it is only the rare case that requires the use of ether. An appraisal of the literature gave me an unfavorable impression for its continued use in the average case.

CHAIRMAN GARLAND Dr. Anderson?

DR. ANDERSON I haven't anything further to add in regard to scarlet fever. I would take the liberty of answering the Doctor's question about the vaccination certificates to high school pupils. As I understand your situation, the child is in the high school having not been successfully vaccinated. The Supreme Court of Massachusetts has ruled that the school committee is within its rights in requiring a parent to renew a vaccination examination certificate as often as once every two months. There has never been any ruling however on how often an attempt at vaccination shall be made but many school committees have interpreted that to the point of requiring that the vaccination attempt be made each year until such time as a successful take shall have been obtained. That has not, however, been ruled upon by the Court. It is merely precedent and as far as I know has never been challenged.

Deceased

HYPERINSULINISM*

BY J. ARTHUR BARNES, M.D.,† AND EUGENE L. RICHMOND, M.D.‡

HYPERINSULINISM, the syndrome first de-
scribed by Harris in 1923, is the condition
in which the pancreas produces so much insulin
that hypoglycemia and its attending symptoms
occur. While the disease entity is probably not
new, the mechanism was not recognized or un-
derstood until the isolation of insulin and its
use to combat diabetes.

Spontaneous hyperinsulinism is to be distin-
guished from spontaneous hypoglycemia which
is merely a descriptive term indicating the low-
ering of the blood sugar which may be induced
by a variety of causes. Hyperinsulinism is con-
sidered to be due to overactivity of the islands
of Langerhans and this overactivity may be
due to diffuse hyperplasia or to adenoma forma-
tion.

The clinical picture of hypoglycemia is
familiar to all who have had experience with
the use of insulin. It is only recently that
disturbances of the pancreas other than hypo-
function of the islands of Langerhans with its
anatomic changes of atrophy and production of
diabetes have been reported. There have been
increasing observations of spontaneous hyper-
function associated with hypertrophy and
adenoma of the pancreas with the production
of hyperinsulinism. It is apparent that the
sequence, hyperfunction, hyperplasia, tumor
formation, aplasia destruction is manifest in the pancreas
as with the earlier studies of the thyroid and
the pituitary.

In a résumé of the cases reported it is stated
that most patients presented a history of grad-
ual onset with symptoms varying from hunger,
weakness, dizziness and a feeling of apprehen-
sion to that of momentary loss of consciousness
with associated automatic movements lasting
from a few seconds to several moments. These

symptoms all followed a long starvation period
at first and were especially common before
breakfast. They were likewise often seen when
severe muscular exercise directly preceded a
meal. They usually disappeared or could be
aborted by the ingestion of food. There was a
tendency for the attacks to become more fre-
quent and more severe until, by the time the
patient was seen, convulsive attacks associated
with coma were common. Another finding
which was marked in several patients was a def-
inite mental deterioration. A striking feature
in the typical history is that the patient usually
notices the association between attacks and
hunger. The symptoms of the late cases are
identical with those of insulin shock, weakness,
headache, nervousness, anxiety, fatigability,
coldness, numbness of the extremities, epigastric
distress, tremor, profuse perspiration and visual
disturbances. In short the symptoms are so pro-
tean and indefinite that the busy practitioner is
too liable to dismiss the case as one of hysteria
or nervousness, and prescribe one of the many
mild sedatives and is quite surprised that these
are of no benefit and the patient progresses to
the typical attacks of actual coma. Those cases
seen with convulsions in which the attack is
preceded by typical premonitory symptoms of
dizziness, chilliness, profuse perspiration, a crav-
ing for sweets, an involuntary cry or a fall, with
increasing drowsiness followed by coma with
muscular twitching, at first limited to the hands
or face followed by generalized rigidity and
salvation are often mistakenly diagnosed as
epilepsy or the convulsions of a brain tumor.
In one series the diagnosis of idiopathic epilepsy
was made fourteen times in a series of sixty-
five reviewed cases of spontaneous hypoglycemia.
Because of this close clinical relationship it is
strongly recommended that all epileptics have
blood sugar studies as there seems to be a small
number whose convulsions are secondary to hy-
poglycemia.

Physical examination usually reveals nothing

Read before the Worcester District Medical Society at
St. Vincent Hospital, December 1, 1934.

†Barnes, J. Arthur—Attending Surgeon, St. Vincent Hospital,
Worcester. Richmond, Eugene L.—Assistant Attending & rec-
ord. St. Vincent Hospital, Worcester. For records and addresses
of authors see "This Week's Issue," page 40.

of any significance. There is a tendency for the patients to be overweight due to the excessive intake of carbohydrate. Blood pressure readings are commensurate with the age of the patient. Basal metabolic readings are not significant although in many cases this was not done due to the danger of a long fast.

The dextrose tolerance curve varies. In the functional group the elevation of sugar level is small, rarely an increase of so much as fifty per cent in one hour and a drop to the pre-fasting level or below in three hours. Yet there have been five reported exceptions to this observation. In the majority of cases with adenoma the elevation is in excess of normal and the fall to the low level is delayed. However, there have not been enough observations to use this test to differentiate the three types of pathology in the pancreas, hyperplasia, adenoma and cancer.

Epinephrin is supposed to exert an hyperglycemic effect by the liberation of sugar from the glycogen in the liver. In normal individuals the injection of 0.6 cc of a 1:1000 solution of adrenalin causes an increase in blood sugar of thirty-five to forty-five mgm within forty-five to sixty minutes not returning to the normal level for two hours. Theoretically one would expect that adrenalin would be efficacious in raising the blood sugar level in cases of hypoglycemia of pancreatic origin and not in cases of hepatic origin. In the reported cases the elevation is more prompt than in normal cases. The rise is almost as high and there is a more rapid drop to the pre-injection level. Because of this fact the administration of adrenalin in an attack is very beneficial but it must be followed at once with ingestion of glucose to maintain the elevation.

Pituitrin, although it has some antagonistic effect on the action of insulin, has not proved of value in warding off attacks.

Thyroid extract is somewhat more potent. If enough extract is given to maintain a metabolic elevation of twenty per cent, the tendency to attacks will be checked. The disadvantages of this form of therapy are obvious.

An accepted classification of the causes of hypoglycemia is as follows:

(1) Excess of insulin as a result of therapeutic injections of insulin, of tumors and hyperplasia of the pancreas or of functional hyperinsulinism.

(2) Lack of opposing secretions may result from diseases of the suprarenal glands, tumors of the anterior or posterior lobe of the pituitary or from myxedema.

(3) Lack of glycogen.

This lack may result from destruction of reservoirs, disease of the liver or wasting of muscles, from abnormal secretion of sugar in starvation and intoxications from phosphorus or arsphenamine poisons.

(4) Interference with regulating center. This may result from disease affecting the pons or from overaction of the vagus nerves.

Accepting the facts that studies of the blood sugar in the fasting state and for dextrose tolerance curves and that the therapeutic use of dextrose reasonably establishes the occurrence of hyperinsulinism, the problem of determining the nature of the pancreatic pathology presents a great many difficulties. A localized malignant growth may be found. The impossibility of resolving the diagnostic uncertainty of the underlying pancreatic pathological changes and of thereby determining the operative procedure make the decision for operation quite difficult as only exploratory intervention can be done and the prognosis is uncertain. Medical treatment by excessive feeding, especially carbohydrates, is only a temporary procedure and in many cases, as with the present reported one, will not relieve the attacks. Then, too, there is always the possibility of increased hyperfunction due to the stimulation of forced glucose feeding which will speed up this progressive disease entity.

From the few papers concerned with the intensive study of these cases it is apparent that there is no striking difference between those with an adenoma and those with no demonstrable pancreatic lesion. For this reason it is suggested that all patients be given a trial at medical treatment for a suitable interval. There is a very grave note of warning suggested in the report of one author (Wilder) who found two cases of carcinoma with metastasis in fourteen cases. This ever-present danger coupled with the fact that a medical régime has not been accepted by all men as being satisfactory, many recommending frequent high carbohydrate feedings, others high fat, low carbohydrate, would seem to indicate that one cannot dally too long. The reasoning of those advocating a high fat diet seems to be more sound as repeated carbohydrate feeding would tend to cause excessive production of insulin by a gland already hyperfunctioning. This is well borne out by the clinical history of those patients who early recognize the value of food especially quickly assimilated carbohydrate and their rapidly progressive decline.

Another (Ryneerson) states that it would seem advisable to subject all patients with this syndrome to abdominal exploration since there is no method of diagnosing it preoperatively. He bases his premise on the belief that all these tumor cells are neoplastic with some resemblance to island cells and producing insulin or some related substance. He further states that so many carcinomata give no warning signs, yet here is a type that shrieks for it.

Experience with surgical treatment to date, however, has not been entirely satisfactory. When an adenoma has been found and removed a cure has resulted, but if a tumor has

not been found and if resection of the pancreas has been attempted, the benefit has been slight. However, many authors feel that the gland can be resected with safety. The probable cause of the hyperplastic cases is that not enough gland substance has been removed, again paralleling early thyroid surgery.

We are indebted to Dr. M. Gene Black for a complete medical and laboratory investigation during the eighteen months previous to our investigations when the patient consulted her at irregular intervals. During this period the patient had consulted numerous physicians who had told her that her symptoms were due to a "nervous condition." Medication for this nebulous diagnosis had given no relief.

Report of a case

K. P. B., single female aged thirty-five

Past history uneventful but for a D. & C. and cauterization of the cervix for pelvic pain and vaginal discharge three years ago. Blood count, blood pressure and urine were negative at that time. Blood chemistry studies were not recorded.

The exact beginning of the present illness was difficult to determine because of the vagueness of the symptoms. Eighteen months ago she sought medical relief for a fall. Blood pressure, blood count and urine were negative at this time. The patient was extremely nervous and emotionally unstable. All manipulations causing extreme apprehension. In retrospect this was probably the beginning of the present syndrome.

For approximately one year the patient has been suffering from fainting and sinking spells lasting from ten to fifteen minutes during which there was loss of consciousness with clonic and tonic contractions. Recovery was always spontaneous leaving the patient fatigued and exhausted. There was no conscious association with the taking of food to allay or prevent the attacks although the patient stated that she has always had a craving for sweets. Has been consuming candy in larger quantities lately and always has some with her. In spite of the increased carbohydrate intake there has been no increase in weight. The attacks have had a definite periodicity occurring either at ten A.M. or three P.M. with luncheon at twelve noon. They have been of increasing frequency and duration. Examination at this time revealed nothing significant. There was slight tenderness in the L.U.Q. In addition to the fainting spells the patient complained of weakness, fatigue, coldness, irritability and insomnia. There was definite emotional instability as indicated by frequent crying spells and marked apprehension during the examination. Basal metabolism was +3 and +4 in repeated tests. Previous basal metabolism tests one year ago revealed +9 —35 —75.

The patient was placed upon a high carbohydrate diet with marked immediate relief of symptoms. Subsequent blood sugar determinations were as follows:

Fasting	6 00 A.M.	30 mgm per 100 cc blood
	7 30 A.M.	83 " "
	4 30 P.M.	90 " "
	10 00 P.M.	68 " "
	11 00 P.M.	41 " "

on different days without controlled high carbohydrate diet.

On admission to the hospital blood sugar fasting specimen was sixty mgm. After the ingestion of 100 Gm of glucose, the readings of the glucose tolerance test were the following one-half hour

eighty mgm one hour seventy-eight mgm two hours eighty-four mgm three hours ninety-four mgm. four hours eighty mgm. At no time was there any overflow of sugar into the urine.

During the test the patient had two typical attacks during which there was generalized rigidity of the entire body, eyes fixed, face and mouth rigid. The B.P. remained normal and there was no change in the pulse rate. The patient did not respond to questions or pressure over the supraorbital nerves. The first attack was of ten minutes duration the second of fifteen. Recovery was spontaneous followed by lassitude and prostration and alternating periods of crying and forced gaiety. This type of curve as contrasted with the reported observations would indicate the pathology in the pancreas to be of the hyperplastic type. Yet of those reported five were marked exceptions to this and in one of them carcinoma was found at postmortem.

She was placed upon a high carbohydrate diet and the following morning the blood sugar was 115 mgm. One-half hour after the injection of 0.5 cc. 1:1000 adrenalin the blood sugar was 150 mgm which persisted for one hour. Inasmuch as epinephrin is supposed to exert its hyperglycemic effect by the liberation of sugar from the glycogen in the liver it would indicate in this case that the patient had adequate stores in the liver and that it was readily available and that the hyperinsulinism was not due to liver pathology.

Basal metabolism tests ruled out any thyroid disorder as the basic cause and there were no stigmata to indicate pituitary dysfunction.

Because of the increase in symptoms and the progressive nature of the disease as seen in many reported cases diagnosed only at the autopsy table a loss of fifteen lbs. in six weeks and hearing in mind the warnings issued by authors reporting well-developed malignant growths exploratory intervention was decided upon even though a clean-cut differentiation of hyperplasia, adenoma and cancer could not be predetermined.

At operation adequate exposure was obtained through the gastrocolic omentum. Thorough palpation of the entire gland failed to reveal any discrete adenomata. The major portion of the gland was softer and paler than in the normal organ. At the extreme tail of the pancreas adjacent to the spleen there was a shotty like feel to the gland. Approximately two inches of the tail was then resected.

Following the operation and four hours after the intravenous injection of sixty Gm. of glucose the blood sugar was 333 mgm. with 0.5 per cent in the urine. Two days later the sugar was 178 mgm on forced carbohydrate feeding. The persistence of sugar in the blood was an encouraging sign that the rapid formation of insulin had been checked.

Three days postoperatively the patient developed a diffuse bronchopneumonia followed by acute dilatation of the stomach and died. Autopsy permission was not obtained.

Pathologic report

Section through the pancreas shows an increase in the interstitial fibrous tissue and an irregular infiltration of lymphocytes about the islands. There were no marked abnormalities histologically involving the islands themselves or the sections studied. From these sections it would appear that the hypersecretion was due to overactivity of normal appearing epithelium.

There is definite need for more elaborate studies of this chemical entity. This paper is intended primarily to bring the syndrome before the profession so that earlier diagnosis of this condition can be made. Unquestionably it is

much more frequent than the literature would indicate, and a plea is made for a more thorough investigation of those obscure cases that we all too readily dismiss as being functional in origin

BRAIN ABSCESS AS A COMPLICATION OF SEPTIC PLEUROPULMONARY DISEASE*

BY D A NICKERSON, M D †

INTRODUCTION

THE unexpected, sudden appearance of symptoms of suppurative disease of the brain as a complication of septic pleuropulmonary disease has long been recognized. Why the brain is attacked more frequently than the other organs has always been a puzzling question and the relative rarity of metastatic abscesses in acute septic conditions, such as endocarditis, makes it even more difficult to understand. Many theories have been advanced, but none have been entirely acceptable. Schorstein¹ felt that in acute septic diseases, the brain has a greater resistance, while in chronic pulmonary disease, it is not so fully protected as other organs by locally formed antitoxic agents. Eagleton² asserts that the cerebral metastases from the lungs are primarily of venous or thrombotic origin as contrasted with abscesses of embolic or arterial origin in acute septic cases. He feels that pulmonary disease favors the thrombotic process in the cerebral veins, and substantiates his views by Arnold's³ experiment. The latter injected foreign material into the larger neck veins and by producing a positive intrathoracic pressure found the material in the cerebral veins. This was explained as a retrograde venous phenomenon, but the relatively minor venous return by the azygos veins refutes this view. Gardner⁴ felt that long-continued coughing, by producing a positive intrathoracic pressure, lowers the cardiac output temporarily, and a consequent transient ischemia of areas of the brain develops which tends to lower cerebral resist-

ance. Proof of this momentary ischemia is seen in the temporary unconsciousness occasionally noted in vital capacity tests. Parker⁵ questions whether it is possible that the tissues of the lung and brain have something in common whereby brain tissue acts as a favorable soil for metastases of suppurative or carcinomatous processes of the lungs.

Following Schorstein's paper, cases of septic pleuropulmonary disease with subsequent brain abscesses have been divided into several types dependent upon the pathological lesion in the lung, chiefly, lung abscess, empyema and bronchiectasis. Such a classification is necessarily arbitrary since the pathological boundaries are not always clear and many cases combine several types of lesions. Many authors do not separate their cases properly, so that figures regarding the incidence of the various processes in the lung and metastatic cerebral abscesses are subject to criticism.

MATERIAL

This report is based upon a study of sixty cases of brain abscess and 538 cases of septic pleuropulmonary disease occurring in a series of 10,502 autopsies performed in this laboratory over a period of thirty-nine years (1896-1934). This has been done in an attempt to establish the incidence and location of brain abscesses associated with septic disease of the lung and pleura.

Of the sixty cases of brain abscess, twenty-seven (45 per cent) were secondary to otogenic infections, a figure in accord with most writers. Twelve cases (20 per cent) were secondary to disease in the lungs, six cases (10 per cent) were associated with septicemia, five cases (8.4 per

*From the Mallory Institute of Pathology Boston City Hospital.

†Nickerson D A—Assistant in Pathology, Mallory Institute of Pathology Boston City Hospital. For record and address of author see "This Week's Issue" page 240.

cent) occurred with acute endocarditis two cases (3.3 per cent) were consequent to septic disease of the orbit and eight cases (10 per cent) were sequelae of various other diseases.

In correlating these figures with the analysis of 538 cases of pulmonary disease only those cases where examination of the head was done of which there were 180 cases, are included in this study. Seventy-four cases of lung abscess showed eleven brain abscesses, a percentage of 14.7. Sixty-six cases of empyema showed but one cerebral abscess, a percentage of 1.5. Forty cases of bronchiectasis showed no cerebral metastases.

DISCUSSION

Table 1 gives the essential details of the twelve cases of cerebral abscess which occurred as sequelae of suppurative disease of the lung.

is higher than that usually quoted. Seborstein¹ found that thirty-two (62 per cent) were multiple and nineteen were single. Eagleton² in a review of the literature estimated that 45 per cent were single. Parker³ found that his fourteen cases were evenly divided, seven being single and seven multiple.

There appears to be a slight predominance of localization in the parietal lobe in this group, four of the nine solitary abscesses being found in this area. There was but one abscess found in the frontal lobe, which indicates that localization here is a rarity in contrast to the commonly accepted belief. Of interest is one case involving the cerebellum as this is an unusual site, Groth⁴ stating he had never seen one.

As to the side of the brain involved no direct relationship existed between it and the side on which the primary lung pathology was found.

TABLE 1

No.	Sex	Age	Type	Brain Abscess		Lung Abscess	
				Location	Type	Type	Location
97-378	Male	20	Single	Left Frontal	Single	Single	Right Apex
99-69	Male	7	Double	Right Occipital	Single	Single	Right Apex
01-29	Female	35	Single	Right Cerebellum	Single	Single	Left Base
02-49	Female	42	Multiple	Right Parieto-Occipital	Multiple	Multiple	Throughout
02-179	Female	58	Single	Throughout	Empyema	Left	Left
06-161	Female	9	Single	Left Basal Ganglia	Single	Single	Left Base
24-122	Female	26	Single	Left Parietal	Multiple	Multiple	Right Base
24-173	Female	41	Single	Right Parietal	Single	Single	Left Apex
26-164	Male	36	Multiple	Cerebellum (Uvula)	Single	Single	Left Apex
28-83	Male	27	Single	Throughout	Bilateral	Both Bases	Both Bases
32-465	Male	50	Multiple	Left Parietal	Multiple	Left Base	Left Base
33-7	Male	32	Single	Throughout	Single	Right Apex	Right Apex
				Left Parietal	Multiple	Right Lung	Right Lung

and pleura. Of these, seven cases (58 per cent) followed single lung abscess, four cases (33 per cent) were associated with multiple lung abscesses. One case was secondary to empyema. These figures are in direct contrast to Seborstein, who collected sixty-nine cases, nineteen of which were his own. He found bronchiectasis present in thirty-eight cases (55 per cent), empyema in fifteen (23 per cent), gangrene of the lung in six (9 per cent) and the remaining ten were evenly divided with abscess of the lung present in only two cases. The figures are in keeping, however, with more recent reports. Cohen⁵ in reporting nineteen cases, found that fourteen (73 per cent) were associated with lung abscess of which ten were single and four were multiple. Four of his cases (21 per cent) were secondary to empyema, and one case (5 per cent) followed bronchiectasis. No cases associated with pulmonary tuberculosis were found in this study, which is in accord with most authors, although Parker³ reports one case and also cites a case secondary to pulmonary actinomycosis.

In this present series, eight of the cerebral abscesses (66 per cent) were single and four multiple. This incidence of solitary abscesses

No age group was preponderantly involved, the cases being quite evenly divided between the first to sixth decade. There was, however, a distinct predominance of the male sex by a ratio of 2.1.

No definite conclusions could be drawn from the bacteriological studies. The otogenic cases showed a predominance of hemolytic streptococci. Those secondary to disease of the lung showed a wide variety of organisms. The septicæmia cases were chiefly hemolytic streptococci, one unusual case, however, was found to have *B. mallei* in the heart's blood and brain. Of the acute endocarditis cases, two showed hemolytic streptococci, and two staphylococcus aureus in the heart's blood.

SUMMARY

1. Sixty cases of brain abscess and 528 cases of septic pleromypulmonary disease have been studied in an attempt to establish the incidence and location of cerebral metastases in suppurative disease of the lung and pleura.

2. Twelve cases of metastatic cerebral abscesses are presented in detail.

3. Of the etiological factors in brain abscess,

CASE 21311

PRESENTATION OF CASE

A thirty-eight year old Chinese-American waiter entered complaining of abdominal pain.

During the past year the patient had gas pains localized to an area about four inches in diameter just below and to the right of the umbilicus. The pain was constant, occasionally sharp, and never radiated. At times it produced nausea but never actually caused him to double up or vomit. Three months before admission it became more severe and more constant. It bore no relation to meals but if he ate a hearty meal it would become more severe. His appetite, however, remained good. The pain was relieved in three ways: (1) pressure over the painful area, following which he could feel and hear the gurgle of gas passing, (2) a bowel movement, (3) lying on his right side with his knees slightly flexed. There had been no change in his bowel habits except that he had used mineral oil for the past three weeks on the advice of his physician. There was no pain associated with his bowel movements, nor had he ever noticed any bloody, tarry or clay-colored stools. During the past three months before admission he occasionally felt feverish and stated that on one afternoon a week before admission he had had a temperature of 102°. He had never had cough or hemoptysis. He had frequent night sweats during this illness. He had lost approximately thirty pounds in weight during the past three months. His present weight was about ninety-five pounds.

His father and mother, both over seventy, were living and well. One brother and sister were living and well.

He had been married twenty-one years. His wife and three children were living and well.

There was no history of carcinoma, diabetes or tuberculosis. Except for an appendectomy fourteen years before admission the past history is non-contributory.

Physical examination showed a thin man in no acute distress. There was evidence of marked loss of weight. The heart and lungs were negative. The abdomen was soft and very tympanic except in the right lower quadrant, which was completely occupied by a firm, elastic, slight-

ly tender, fixed, irregular mass. The right lower quadrant appendectomy scar was fixed to the mass. The right thigh could not be fully extended without pain. There was one small gland in the right axilla. His fingers were slightly clubbed. The blood pressure was 110/60. The temperature was 99.2°, the pulse 95. The respirations were 25.

Examination of the urine was negative. The blood showed a red cell count of 4,600,000, with a hemoglobin of 85 per cent. The white cell count was 13,000, 77 per cent polymorphonuclears. A Hinton test was negative. A barium enema passed without delay to a point in the transverse colon just distal to the hepatic flexure. At this point a loop of small bowel was observed to fill. There was a definite obstruction at this point to the passage of barium onward into the colon but the loops of small bowel continued to fill. A small amount of barium did pass on to outline poorly a very spastic cecum and ascending colon. The mass was found to overlie the constricted area, which was three inches in length. The edges of this constriction were shelved and the margins showed marked irregularity. A chest film was negative. A flat abdominal film was negative.

On the third day through an incision just inside the right anterior superior spine an abscess cavity was broken into by blunt dissection without entering the peritoneal cavity. A tube was sutured into the cavity and the wound closed. A culture of this abscess showed bacillus coli and non-hemolytic streptococcus. He ran a very slightly septic temperature, ranging between 99° and 101°. Approximately three weeks after the first operation the incision in the flank was enlarged posteriorly in order to give him adequate and more dependent drainage. Ten days later laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK: We might stop for the moment and review the information we have been given down to the laboratory examination.

"During the past year the patient had gas pains localized to an area about four inches in diameter just below and to the right of the umbilicus." Three months before admission the pain became more severe and continuous. I do not know what the writer means by "gas pains." According to my own conception it is a pain that comes and goes, more like colicky pain. The more you talk about steady pain,—I dissociate it a little bit from the so-called gas pains—the more we think of an inflammatory process. It is conceivable and quite likely that both are associated and that he may have something interfering with the normal peristaltic activity, presumably of the large bowel, because the level of the pain is below the level of the umbilicus and in addition he may have a localized inflam-

matory process somewhere in the right abdomen giving the more constant pain and soreness.

His procedures for getting relief are interesting and significant. "(1) Pressure over the painful area following which he could feel and hear the gurgle of gas passing." I do not know just how much importance to stress on the pressure of the hand over that area. I presume his relief of pain came in some way during manipulation, causing him to pass gas. "(2) A bowel movement." That is a perfectly definite concrete thing. He has pain, has a bowel movement, and then has relief from pain. That to me means that he probably has an obstructing lesion in the large bowel. "(3) Lying on his right side with his knees slightly flexed." The only significance that I can put on that is that he probably has an inflammatory process. When he lies down and relaxes the abdominal muscles by flexing his knees, he gets some relief from the discomfort he would otherwise have from the more tense muscles. To me that suggests that in addition to the obstructing lesion of the bowel there must be some inflammatory process present. There is very little in the rest of the present illness except the fact that he has had fever. He knows he had a fever of 102° on one occasion and he has felt feverish at other times. This is wholly in keeping with the conception that there is present an inflammatory process. His loss of weight fits in with either or both.

The next important thing is in the physical examination. The entire right lower quadrant is completely occupied by a firm, elastic, slightly tender, fixed irregular mass. He has an appendectomy scar which seems to be fixed to the mass, also the right thigh cannot be extended without pain. Whether that means that stretching his ileopsoas is the cause of the pain or simply means that in flexing the thigh there is a relaxation of all the abdominal muscles and relief of pain for that reason, I do not know. But I think it is suggestive again of the presence of an inflammatory process. I do not believe that one can thus far draw any conclusion other than to say that it would seem as if this man had an inflammatory process involving the large bowel in such a way as to give him some mechanical interference with a normal bowel activity.

The blood examination gives us no help. Frequently in a malignant disease of the right colon a marked secondary anemia is present. On the other hand one can have it without the secondary anemia so that that picture does not give me any great help, although I confess I am surprised that a man who has been sick as long as he has, who has lost thirty pounds and has been running a fever, should have as high a red cell count and hemoglobin.

He has by barium enema a definite obstruction at the proximal portion of the transverse

colon, when the barium gets around to that point the small bowel seems to fill, the mass overlies the constriction and the lumen of the bowel presents a shelving. That must mean an elevated portion within that area where it is constricted. The constriction is about three inches in length. The negative chest film may or may not be of interest in relation to a subsequent discussion of tuberculosis as a possibility. I mention it now because I think it can be dismissed. Tuberculosis of the bowel may occur in the absence of x-ray evidence of disease of the lungs just as well as in its presence. Diffuse enteritis is practically always associated with tuberculosis of the chest but localized tuberculosis that we see in the large bowel is not.

As we come down to the laboratory notes, I picture a process in the right colon which is a combination of an obstructive with an inflammatory process. That is he may possibly have had some type of inflammatory process which had constricted and obstructed the bowel or he may have had some type of lesion within the bowel which had perforated subacutely and had given him an inflammatory process secondary to the lesion of the bowel itself. A barium enema gives us very definite information. It localizes a lesion just distal to the hepatic flexure, that is the proximal portion of the transverse colon. I presume this man was small and thin, was very light probably, and had a very low transverse colon so that the mass could swing around and seem to be lower down in the bowel than it actually was. The other interesting thing in the x-ray is that as the barium reaches the obstruction the small bowel fills. There is only one interpretation that I can intelligently put on that. Whatever the process is, there must be an opening between the transverse colon at that point and a loop of small bowel which must be adherent to the lesion. In other words, we have an obstructive process involving the proximal portion of the transverse colon to which a loop of small bowel is adherent and between these loops a spontaneous anastomosis has taken place.

What are the conditions that one has to consider in attempting to come to some conclusion as to what the process is? Of course the thing that immediately comes up is carcinoma. I cannot from anything that is in the story exclude a carcinoma of the transverse colon with involvement of a loop of small bowel with secondary abscess. That is a possible explanation for the process. There is nothing about it which is not easily and entirely in keeping with such a diagnosis. Tuberculosis is the next, I think, and most likely. I think it is quite possible that the formation of a fistulous opening between this process and the adjacent coil of small bowel may be more in keeping with a tuberculous lesion than with malignant disease. As

we have already said, a negative chest x-ray means nothing. He has had a suggestion of fever with this for some little time, which might suggest strongly that it is of tuberculous origin rather than malignant disease. According to the description of the x-ray here—and I am quite willing to admit I do not know too much about tuberculosis of the large bowel—but my conception of tuberculosis of the large bowel is not quite in keeping with a constriction the edges of which are shelved. The shelving of the edges of the constriction to me more definitely suggests the possibility of a new growth in the bowel than it does the more diffuse process that one gets with tuberculosis. On the other hand I cannot completely and intelligently exclude it. There are certain other things that one thinks of. I have seen two cases of actinomycosis of the right side following appendectomy, but in each of the cases the interval between appendectomy and actinomycosis was a matter of a few weeks or months. There is an interval of fourteen years here so that the appendix cannot be a source for it. The description of an elastic mass is wholly out of keeping with the board-like mass one gets in actinomycosis and I think that can be dismissed merely after the mentioning of it.

Lymphosarcoma that one sees in the large bowel again must be mentioned and certainly is a possibility. I do not think that that is what it is. Most lymphosarcomas we have seen have not gone on to abscess formation in this way, and while again it is a possibility we may exclude it. Some time ago I happened to discuss at one of these conferences a large intestine case and about two months afterwards I had a very nice letter from a doctor in Nigeria who described a patient with a mass in relation to the right colon due to *entameba histolytica*. This patient is a Chinaman but I believe he has been in this country all of his life. He has not diarrhea, although this does not exclude it.

The other condition that one has to consider is the localized inflammatory process usually termed localized or regional ileitis. This lesion may involve the large bowel. It shows a great tendency to become adherent to adjacent structures, a fistula frequently forms and it is perfectly conceivable that such a process may be present in this man. It is a very unusual condition and, although there is no diagnostic x-ray picture and while none of us have seen many of these conditions, particularly in the large bowel, I do not think one would expect the constriction to have shelved margins. Therefore I would not be content to make that diagnosis.

It seems to me that the reasonable conclusion is that this man has either a carcinoma or tuberculosis of the beginning of the transverse colon with a loop of small bowel adherent to it and with a communication between, and with

the large mass surrounding the entire area largely inflammatory in character.

CLINICAL DISCUSSION

DR ARTHUR W ALLEN. This man was very ill when he came in and had obviously been ill for a long while. He had this enormous mass in his right side which was a good deal more tender I think than the history would lead you to believe. An enthusiastic service had a barium enema done before we saw the patient. We feel that barium enemas perhaps may be dangerous in large bowel lesions in the acute stage with obstruction and although it did this patient no harm and contributed some very valuable information I think perhaps we ought to mention the fact that it is not a good policy to do a barium enema routinely until at least you have had a flat plate of the abdomen. We felt that whatever the original process was in the colon that there was no question he had an abscess in the region of the cecum. So, in spite of any suspicion that we might have as to the original lesion, an incision and drainage of the abscess was done. He responded only moderately well to this operation. His temperature did come down at first but in a few days started to rise again. We were getting quite discouraged about him and finally decided that the only thing to do was re-drain his abscess at a lower level. This gave a very good result evident in his chart and general condition, so that ten days after the second drainage it was possible to go in through a clean incision and resect the entire lesion. As you might imagine it was very adherent to surrounding structures, involving the cecum, ascending colon, terminal ileum, and extending into the psoas muscle, parietal peritoneum, etc. It was possible to remove it all and do a lateral anastomosis and the patient was finally discharged some twenty days after the last operation to a convalescent hospital.

PREOPERATIVE DIAGNOSES

First Operation Pericecal abscess Carcinoma of hepatic flexure
Second Operation Pericecal abscess
Third Operation Carcinoma of the cecum and transverse colon

DR LELAND S MCKITTRICK'S DIAGNOSES

(1) Carcinoma or (2) tuberculosis of the transverse colon with involvement of the ileum

PATHOLOGIC DIAGNOSES

Tuberculosis of colon and ileum
Fecal fistula.

PATHOLOGIC DISCUSSION

DR BENJAMIN CASTLEMAN. The surgical specimen consisted of the entire ascending colon

and a portion of transverse colon and terminal ileum. The anastomosis described by the roentgenologist was a surgical one and not spontaneous as one might infer from the lack of any history. Apparently at the time of his appendectomy fourteen years before the surgeon resected a portion of cecum and anastomosed the terminal ileum to the ascending colon. What Dr. Allen did was to repeat this first operation higher up, i.e., resect the blind end of the ascending colon including the ileocolic anastomosis and perform another ileocolic anastomosis.

Almost the entire section of colon is markedly thickened and constricted. The mucosal surface shows an almost annular zone of irregular ulceration which corresponds to the shelf-like described by x ray. This is especially marked in the distal portion. There is also ulceration of the ileum at the point of anastomosis and at the base of this region there is a fecal fistula that apparently had drained through the psoas muscle and from which a culture of bacillus coli was obtained. Histologic examination showed tuberculosis. This case apparently belongs to the hypertrophic type of intestinal tuberculosis which often shows ulceration with surrounding areas of elevation. It is not the acute form of ulcerating enteritis that is usually associated with pulmonary infection.

DR. ALLEN. We thought that was a spontaneous anastomosis and the x ray people did commit themselves with a diagnosis of carcinoma as the first choice and tuberculosis as the second. I thought it was carcinoma.

DR. RALPH ADAMS. Dr. Langdon Parsons and I went over fifty-two cases of tuberculosis of the cecum from 1924 to 1933. Of these twenty-four were proved pathologically. We were directed to this study by a case that Dr. Parsons had in the Baker Memorial in which it was difficult to differentiate carcinoma of the cecum and tuberculosis. In fifty-two cases of carcinoma of the cecum during the same period four had a preoperative diagnosis of tuberculosis. The most common symptom was pain referred to the region of the umbilicus. An irregular mass with tenderness was found in half of the cases and most of them were fixed to the right lateral wall. A minor point of distinction was that the red blood cell count was not below 3,800,000 in any of the cases of tuberculosis as contrasted with the carcinoma cases, in which the counts were almost all below 3,500,000. A positive guaiac on the stools appeared only five times. This we thought was due to the fact that most of our cases fell within the older groups which tend to have constipation and absence of blood, as against diarrhea and bloody stools in the younger groups. The x ray findings consistently reported spasm of the cecum. These findings were spoken of as a standard defect both in the hospital reports and in the literature. The attempt to confirm the barium enema by a gastro-

intestinal series almost consistently failed and in several cases the diagnosis was not made at the first entry. The most common error was the interpretation of the films as carcinoma of the cecum. We found that one-third of the patients in the age group over thirty-five who had the disease had it in the absence of clinical or x ray evidence of tuberculosis in the chest and only one-third of the cases had clinical symptoms referable to the lungs or chest.

CASE 21312

PRESENTATION OF CASE

First Admission. A thirty-five year old Italian laborer entered complaining of right lower quadrant pain.

Approximately one year before admission he noticed that he was bleeding from his rectum. This hemorrhage continued for four or five days and then disappeared for a period of a month. There was no pain and no other symptoms except for moderate constipation. The hemorrhage continued to appear at intervals until three months before admission, at which time it became continuous more marked at night. Associated with this increased melena there was severe tenesmus, often as much as thirty times a day, each attempt being rewarded by a slight show of watery fecal material and some blood. During the past three months there had been intermittent pain often very severe, which was localized to the right lower quadrant but at times was generalized throughout the abdomen and was often relieved by a bowel movement. There was some pain upon urination, especially on the right side of the scrotum. During the past year he had lost about fifteen pounds in weight.

His family, marital and past histories are non-contributory. There was no history of carcinoma or tuberculosis.

Physical examination showed a thin, undernourished man with evidence of recent loss of weight. His teeth were dirty and carious. There was moderate pyorrhea. The chest showed a few prolonged inspiratory and expiratory sibilant and sonorous rales. There was no dullness. The breath sounds were not prolonged. On rectal examination there was a firm, irregular, fixed annular mass well within the reach of the finger. The finger, however, could be passed through the lumen but the top of the growth could not be reached. The blood pressure was 106/64.

The temperature was 99.6°, the pulse 65. The respirations were 20.

On the day following admission abdominal exploration revealed a firm, annular mass in the upper portion of the rectum. The liver was free from metastasis. Upon incision the perineal reflection from the rectum was found to have extensive glandular enlargements. It was thought unwise to attempt resection of the

growth. The sigmoid was then delivered through the wound and a colostomy performed. Histologic examination of a lymph node and a fragment from the rectum showed no evidence of malignancy.

He had a stormy postoperative convalescence and was finally discharged two weeks after operation to the Huntington Hospital for radium treatment.

Second Admission, four years later

Following discharge he reported to the Huntington Hospital every two or three weeks for radium treatment over a period of six months. A histologic examination of a piece of tissue from the region of the tumor removed at the Huntington Hospital showed no evidence of neoplasm. He did well for the remainder of this interval until a few days before this admission, when he complained of slight pain in the right lower quadrant. There had been no nausea or vomiting but he had bled occasionally from his colostomy. His stools, however, were normal in consistency.

Physical examination showed a hernia in the lower end of the abdominal wound. The abdomen was soft. In the right lower quadrant there was a slightly tender movable mass approximately 4 centimeters in diameter.

His chart was normal.

Examination of the urine was negative. The blood showed a white cell count of 13,800.

On the third day through a right oblique abdominal incision a dilated, thickened adherent appendix was removed. Exploration revealed that the mass felt before operation was in the cecal wall and mesentery forming a tumor approximately 5 by 3 centimeters. The rectal tumor had completely disappeared except for induration in the pelvic floor. At the point where the rectum passed through this there was a narrow stricture. The liver was negative. The ileocecal glands were enlarged and one was removed. Histologic examination of the glands and appendix showed lymphoid hyperplasia and healed appendicitis respectively.

He did fairly well postoperatively and was discharged two weeks later.

Final Admission, fifteen months later

Following the last admission the mass in the right lower quadrant enlarged and receded in size and because of this the patient thought it was gas. The pain, however, continued as a dull steady ache. One week before admission he began having colicky pains in the right lower quadrant which lasted about fifteen to twenty seconds and recurred every five minutes. His colostomy had continued to function satisfactorily although he did have some constipation close to the colostomy opening. Abdominal examination showed, in addition to the colostomy and right lower quadrant scar, a hard, irregular, movable, egg-sized mass apparently intraabdominal but located just beneath the appendectomy scar.

The temperature was 97°, the pulse 80. The respirations were 20.

Examination of the urine was negative except for an occasional white blood cell and many brown granular casts. The blood showed a red cell count of 6,000,000, with a hemoglobin of 80 per cent. The white cell count was 10,900, 79 per cent polymorphonuclears. Two stool examinations gave negative guaiac tests. A smear was negative for tubercle bacilli. A Hinton test was negative.

X-ray examination was unsatisfactory because the patient expelled the enema.

On the fourth day operation was performed, and the cecum, ascending colon and terminal foot of ileum were resected. He did poorly postoperatively, developed signs of bronchopneumonia and died on the fifth postoperative day.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR W. ALLEN: This is such a typical story of carcinoma of the rectum that, except at these clinico-pathologic conferences, almost any other possibility would be precluded.

Of course this is a fairly young man, only thirty-five, but carcinoma of the rectum may happen in the twenties and I believe cases have been reported in the teens, thirty-five is not too young an age to have such a disease appear. He had been well until he started to bleed from his rectum. He bled a little for a few days and then stopped and then bled intermittently up to three months before he came in, when he began to bleed daily and had tenesmus requiring relief at the toilet many times a day. That is a very typical story for carcinoma of the rectum. This growth was easily felt by the examining finger and some lumen was still present, but it was not possible to get a proctoscope or finger through it. Such tumors are hard and indurated and frequently there is so much infiltration, either inflammatory tissue or malignant disease, around them that it is often impossible to reach the top of the growth. The pain on urination would lead one to suspect that the metastases had perhaps encroached upon the urinary tract, and further confirms the suspicion of a very advanced carcinoma of the rectum with marked pelvic metastases.

He had lost fifteen pounds in weight, probably due to diarrhea.

At operation the liver was free of metastasis. It is not at all uncommon in carcinoma of the rectum where the pelvis may be full of metastatic nodules to find that the disease has not reached the liver. Obviously the operator felt that the tumor was not removable and did a colostomy above the growth which in itself probably would not have affected the tenesmus very much. A point which I think one might speak of with colostomy above a low growth, one that is creating constant desire to defecate, is that colostomy does not always relieve tenesmus very

much. It does help if in addition to the colostomy one divides the sphincter muscles so that there is a continuous discharge, thus eliminating the urge to evacuate the rectum.

The fact that we had a negative pathologic report from the lymph node and from a biopsy from the rectum seems a little queer and makes us wonder, that is, if it was negative so far as malignant disease is concerned, and makes us wonder what type of lesion we could be dealing with if it is not carcinoma. I am not worried about the biopsy from the rectum because in these growths where there is more or less stricture it sometimes is not possible to get a specimen from the growth itself. One may easily take a bit of mucous membrano where it is folded over the edge of the growth and that naturally would not show any of the disease, for this reason occasionally rectal biopsies do turn out to be negative so far as malignant disease is concerned even if the diagnosis is clinically evident. The fact that the lymph node was not involved makes me a little bit more suspicious because one would expect the lymph node to show metastatic disease. However I believe that I will so far have to conclude that this man had carcinoma of the rectum. He was treated at the Huntington Hospital with radium. I believe that he would not have had six months of radium treatment at the Huntington Hospital if the Huntington Hospital as well as this hospital had not thought that this man had malignant disease.

"A histologic examination of a piece of tissue from the region of the tumor showed no evidence of neoplasm." One wonders how that specimen was removed, whether from the tumor itself or whether again they got a piece of normal mucosa.

The dilated appendix is an important factor and means that he had obstruction beyond the cecum somewhere because the appendix is distended with gas only where there is obstruction beyond the cecum.

It is a little disturbing that we have no note about the rest of the abdominal exploration. To what was his large bowel pain due? Was it due to a poorly functioning colostomy which might have given him backing up in the rest of the colon or has he a lesion which was not palpated somewhere else in his colon between the cecum and colostomy? We know that he had bled several times through the colostomy. If that is true it is an important statement but practically all colostomies have a tendency to ooze a little bit from the exposed mucosa at times. Often there will be a little blood on the dressing. It may be an accurate story. If it is accurate, it is important, because if he has bled he has a lesion somewhere else in his colon. The histologic examination of the colon showing lymphoid hyperplasia is again not necessarily

against the fact that this lesion in the bowel is carcinoma. Obviously the operator felt that this was not a malignant lesion in the cecum and felt it was an inflammatory lesion or he would have prescribed something more radical than appendectomy for relief of the tumor of the cecum in the presence of what appeared to be an apparently healed lesion in the pelvis.

"In the right lower quadrant there was a slightly tender movable mass approximately four centimeters in diameter." One would draw the conclusion from this description that this mass in the right lower quadrant had not increased tremendously in size during the past fifteen months, which is somewhat surprising.

His red blood cell count is put down in large figures, 6,000,000, and the hemoglobin 80 per cent, which coincides perfectly well with Dr. Adams' report on tuberculosis of the cecum but not very well with carcinoma of the cecum. We expect anemia associated with carcinoma of the cecum.

We have, then, a patient with a perfectly typical story for carcinoma of the rectum who apparently, after a colostomy, was successfully treated with radium so that he had a respite of four years. I am not sure how many inoperable carcinomas of the rectum are successfully treated with radium but my impression is that they are not very common. The percentage I am sure is very much less than the percentage of cures of carcinoma of the cervix treated by radium. Then he comes back four years afterwards apparently with a mass in the region of the cecum which again is negative to biopsy so far as malignancy is concerned and if we are to believe his story he probably has bled some from the colostomy. The statement that this growth in the region of the cecum did not seem to increase greatly in fifteen months may not give us a true conception of affairs because it may have been a slowly growing lesion of one sort or another. I would feel that this man had probably multiple polyps in his large bowel. The first one to become malignant being in the rectum afterwards another lesion in the colon, probably independent of the original tumor. Multiple malignant lesions in the colon are not too uncommon developing on polypi, so I should feel that that would perhaps explain the story better than any other condition and that he had in addition to this mass in his cecum something in the colon between that and his colostomy. I do not think that tuberculosis could possibly explain this picture. Time is short and I can not go into all the details on that. I do not believe lines would explain it. I cannot imagine any type of inflammatory condition that would explain the original condition. It is possible that the second lesion could be non-specific granuloma (regional ileitis) but I think that is unlikely. Here is a man with a carcinoma tend

ency possibly, and there is no reason why he should not have multiple lesions. Lymphosarcoma has to be mentioned as a possibility and that might be the second best bet, but I should adhere to the diagnosis of carcinoma as the first

CLINICAL DISCUSSION

DR LELAND S MCKITTRICK I did not remember having seen this man until I was just shown the record. I saw him in 1924 and treated him with radium and I remember him because I thought he had a carcinoma of the rectum and later all evidence of disease disappeared, but he could not be recorded as a cure because we did not have a positive pathologic report. He had a fixed growth, very hard, which I had never at that time seen cured by radium, nor have I since.

CLINICAL DIAGNOSIS

Preoperative Hypertrophic tuberculosis of the cecum

DR ARTHUR W ALLEN'S DIAGNOSIS

Carcinoma of the large bowel (multiple)

ANATOMIC DIAGNOSES

Amebic granuloma of the cecum

Operation wounds Resection of the cecum
 Ileocolic anastomosis
 Colostomy

Bronchopneumonia

PATHOLOGIC DISCUSSION

DR BENJAMIN CASTLEMAN The preoperative diagnosis at his last operation was hypertrophic tuberculosis of the cecum. The surgeon found a firm tumor which felt like carcinoma involving the cecum. The tumor was firmly adherent in the right flank. No metastases to the liver or tubercles on the peritoneum were seen. Some of the mesenteric glands

were enlarged. The surgeon's postoperative diagnosis was also tuberculosis.

The specimen consisted of the cecum, ascending colon and a portion of terminal ileum. Almost the entire cecum was replaced by an annular, very firm, ulcerated granulomatous mass about seven centimeters in length. The cut surface of the tumor was hard, white and fibrous. Histologic sections of the wall of the ulcerated area showed a layer of granulation tissue, the superficial portion of which was necrotic, while the deeper portions and the dense fibrous tissue below showed a marked chronic inflammatory reaction, the predominant cell being the eosinophil, although there were moderate numbers of lymphocytes and plasma cells. In a few places along the inner margin of the necrotic granulation tissue definite entamebae histolyticae were seen, one containing many red blood cells.

This case is quite similar to the condition called "amebic granuloma" by Gunn and Howard* of Stanford University. They reported three cases of amebic granulomatous lesions of the large bowel, all giving symptoms, signs and x-ray appearances of carcinoma, and all called carcinoma clinically. Two of their cases showed involvement of the cecum and the other of the transverse colon. In this part of the country where amebic infections are so rare one almost always thinks only of the dysenteric form and rarely hunts for amebae in the stools except in cases of severe diarrhea. It certainly was not suspected in this case and no search of the stools was ever made.

This case also brings up the question of the reported cures of inoperable cancer of the colon by x-ray and radium. I feel certain that some of them, especially those in which a biopsy was not done, might well have been amebic or other types of granuloma.

Unfortunately we were not able to examine the rectum, but there is little doubt that the original lesion there was identical.

*Gunn H and Howard N J. Amebic granulomas of the large bowel. J A M A 97:166, 1931.

THE PREVENTION OF POSTVACCINATION ENCEPHALITIS

POSTVACCINATION encephalitis has been a subject of considerable interest in recent years and occasional cases have been reported in the American literature, seventy five in all, according to Baner¹, including his own case, a six year old girl who made a complete recovery. The course of the disease is stormy and the prognosis grave although, when not fatal, complete mental and physical recovery is the rule. Thus seems surprising in view of the pathologic picture, consisting of adventitious and periventricular round cell infiltrations distributed throughout the brain and cord with myelin degeneration about the smaller vessels.

Of especial interest however, is Baner's advice as to the prevention of postvaccination encephalitis, divided, according to clinical evidence, under three heads. First, the rarity of postvaccination encephalitis in infants under one year of age indicates that infants are not

apt to be sensitive to virus in these early months of life, and the same holds true of secondary vaccinations at any age.

Secondly, if further desensitization to virus has been accomplished by other immunizing agents, such as diphtheria toxoid, there is still less chance of developing encephalitis. Vaccination performed too soon after the toxoid infection, however, particularly if alum precipitated toxoid is used, will probably not be successful, at least a month must be allowed to elapse.

Thirdly the single short scratch or puncture method of vaccinating should be employed, as this allows the minimal effective amount of virus to enter the skin and desensitize the individual before its multiplication reaches the amount of the large doses administered by other methods.

THE BOSTON CITY HOSPITAL

THE way in which a large and loosely organized public institution may be exploited for private gain is suggested by the recent charges of the Boston Finance Commission against the City Hospital. Apparently there have been gross waste and theft of materials, equipment and food on a fairly large scale, and charges of lax discipline, excessive personnel and political interference in the hiring of employees have been made, whether or not those charges can be substantiated.

Certain figures, however, are difficult to explain. Thus it is stated that Bellevue Hospital in New York, feeding 1253 more persons daily than the Boston City Hospital, annually uses 50,000 pounds less meat and 25,000 pounds less butter. The Boston hospital has 13 employees for every 10 patients, as compared with 10 employees to 13 patients in similar institutions in other cities.

Further findings of the commission are as follows:

In order to stop the present thieving and to prevent interlopers from having the run of the hospital and use of the employees' dining rooms, a stricter control of the entrances and exits should be established.

Automobile parking on the grounds constitutes a fire menace.

Excessive personnel is due to the fact that many temporary employees furnished from the mayor's office are unfit or refuse to do their work, necessitating additional help. (This statement the mayor has denied.)

The labor turnover is greater than in any other city department except, perhaps the department of public works.

Long and unwarranted delay in the opening

of the new \$400,000 kitchen unit was partly responsible for the waste in foodstuffs

A business manager ought to be appointed with full responsibility and control over the business administration of the hospital

Authority over and responsibility for the employment of employes other than the surgical and medical staff should be vested in the various heads of the division of administration under the general supervision of the business manager

Efforts should be made to bring about a greater coordination of the operation of the various departments of administration, and also such new construction as may from time to time be in process

A system of adequate and accurate records for the business administration of the hospital should be established and maintained

The findings of the commission deserve serious consideration, and it is probable that they are substantially correct. There is no question that the trustees of the hospital are a body of able and honest men, receiving inadequate recognition and functioning to the best of their ability with inadequate authority to prevent abuses or effect a reorganization

The only real solution of the City Hospital's problems is the appointment of an able administrator who will be free from political influence and vested with enough power to keep the institution above politics

MISCELLANY

DECISIONS OF THE SUPREME JUDICIAL COURT

Appeal, by the insurer in proceedings under the workmen's compensation act, from a decree entered by order of Whiting, J, in the Superior Court

Pierce, J This is an appeal by the insurer from a decree entered in the Superior Court after certification from the Industrial Accident Board, by which payment for services of a physician, George

W Blood, was ordered G L. (Ter Ed.) c. 152 s. 20 reads "During the first two weeks after the injury and if the employee is not immediately incapacitated thereby from earning full wages then from the time of such incapacity and in unusual cases or cases requiring specialized or surgical treatment, in the discretion of the department, for a longer period the insurer shall furnish adequate and reasonable medical and hospital services, and medicines if needed together with the expenses necessarily incidental to such services. The employee may select a physician other than the one provided by the insurer and in case he shall be treated by a physician of his own selection or where, in case of emergency or for other justifiable cause, a physician other than the one provided by the insurer is called in to treat the injured employee, the reasonable cost of his services shall be paid by the insurer subject to the approval of the department. Such approval shall be granted only if the department finds that the employee was so treated by such physician or that there was such emergency or justifiable cause, and in all cases that the services were adequate and reasonable and the charges reasonable.

The reported evidence which, in the main is not disputed by the appellant insurance company discloses the following facts. One Katherine Zombric on October 7 1930 was twenty-two years of age and was then employed as an operative in the mill of the United Rayon Company of Fall River. On that day shortly after she began work in the morning her hair was caught in a revolving shaft and her scalp and back of neck were torn off. She was immediately taken to St. Anne's Hospital. This hospital was incorporated under the provisions of R. L. c. 125 "for the purpose of maintaining homes or hospitals for the care of persons who are ill disabled, invalid or convalescent, and furnishing them with medical and surgical treatment, support and nursing and of maintaining schools for the training of nurses." Shortly after the arrival of the employee at the hospital some one called Dr. George W. Blood "to go down to the hospital on an emergency as quickly as possible." Dr. Blood was a member of the staff of the hospital but was not "on service" that week. However he was subject to call from the hospital for the treatment of emergency cases.

Dr. Blood testified that it was one of the conditions under which he took service at the hospital that he would be subject to calls by the hospital in the event of an emergency arising that the case of the employee was an emergency case and that he was called by the hospital and not by the employee nor by any member of her family that after he treated the employee at the hospital her father came to see him at noon time and he had some conversation with him that he told the father all about the case, how long she would be in the hospital, and that he was perfectly free to get any doctor he wished that the father's first reaction was that he wanted a specialist that Dr. Blood said that he specialized in surgery and the father told

him to keep on and do the best he could with the case. The evidence is not disputed by the insurer that the skin was torn over the right side and back of the neck nor that the severity of the injury necessitated several skin graftings and manipulations of the neck muscles at different intervals nor that the entire recovery of the patient required several months treatment. It is not disputed that the insurer has paid the compensation due the employee under the statute as well as the bill for her hospital treatment from October 7 1930 until November 7 1931 when she was discharged from the hospital.

On October 14 1930 Dr. Blood wrote the insurer Arrow Mutual Liability Insurance Company informing that company of the fact that Katherine Zombric had been injured at the United Rayon Mills on October 7 1930. This letter stated the cause and the result of the injury and concluded "This is a very serious and unusual accident and will probably require several months of treatment and possibly several skin grafting operations. I would appreciate a note from you authorizing such treatment." The insurance company on October 20 1930 acknowledged receipt of Dr. Blood's letter in these words "The accident to the above employee was an extremely unfortunate affair and we are eager to do everything to make possible her recovery. We know that Miss Zombric had been sent to the surgical service of St. Anne's Hospital but had no knowledge as to what member of the hospital staff was in charge of this case. We are pleased to learn that the girl is being treated on your service and we will be happy to cooperate with you in any way. Several days after the accident the Mother Superior of the hospital called on Mr. Joseph A. Parks at the State House and at that time we assured Mr. Parks that we would accept liability because of the hospital care. Dr. J. Newton Shirley of this office is usually in Fall River each week, and I am asking Dr. Shirley to keep in touch with you and to give you any assistance you may need. The record does not disclose that the insurer furnished any medical attention to the employee following its letter of October 20 1930 nor that any physician other than Dr. Blood attended the employee. There is no direct evidence that the employee herself selected Dr. Blood as her physician nor that she authorized any other person to do so on her behalf but the employee's acceptance of the medical services of Dr. Blood for many continuous months clearly warranted the inference if it did not require a finding that the employee ratified and adopted the action of her father in this regard.

It is not contended or found that there was in fact any contract between the insurer and Dr. Blood to pay for the services rendered. The contention of the claimant and the decision of the board are predicated upon the finding or ruling that there existed justifiable cause under G L. (Ter Ed.) c. 152 s. 20 for Dr. Blood continuing his treatment

of the employee as a private patient. The insurer seasonably filed requests for findings of fact and rulings of law. These requests are numbered 1 to 20 inclusive. The reviewing board gave requests numbered 1, 2, 3, 4, 7, 8, 9, 10, 12, 14 and 18 but refused the others. The board in this connection specifically found the following facts under said s 30. On October 7, 1930, at about 7 a m., Katherine Zombric, a girl twenty two years of age and single, sustained a very serious scalp injury which arose out of and during the course of her employment when her hair caught in a revolving shaft. Necessity required that she be sent to the nearest hospital for specialized and surgical treatment. The nearest hospital was the St. Annes Hospital. Dr G W Blood was a member of the staff at the time and had been for a good many years, but he was not on service or duty during the period within which this accident occurred. On account of the exigency, Dr Blood was called by some one connected with the hospital and responded, *rendering emergency service*. Upon the same day, the employee, through her father, selected Dr Blood as her physician. Beginning October 20, 1930, the insurance company furnished no other treatment, and after conferring with the insurance company and receiving a letter from it, Dr J Newton Shirley, employed by the Arrow Mutual Liability Insurance Company, consulted with Dr Blood each week while the employee was under his care.

The board further found that in the circumstances disclosed by the evidence—that Dr Blood came in on the case in the emergency, was asked to continue on the case by the employee's father, together with his correspondence, talk and contact with the insurer or its representative,—there existed justifiable cause under s 30 for Dr Blood continuing his treatment of the employee as a private patient, that the treatment rendered was adequate and reasonable and a reasonable fee for the services of the physician is \$826.

The insurer contends that there was no evidence to support the finding that "upon the same day, the employee, through her father, selected Dr Blood as her physician." The contention is met by the inference, as above stated, that the action of the father was ratified by the conduct of the employee. The insurer further contends that there is no evidence to support the finding that "beginning October 20, 1930, the insurance company furnished no other treatment, and after conferring with the insurance company and receiving a letter from them (above quoted) Dr J Newton Shirley employed by the Arrow Mutual Liability Insurance Company, consulted with Dr Blood each week while the employee was under his care." This contention is based on the position that "The question here involved is whether a physician on the staff of such a general public hospital is entitled to compensation from the insurer for his services to a patient in such hospital in the absence of any contract therefor with the insurer." The insurer further

contends that the following paragraph in the decision of the Industrial Accident Board that "The Board, under the circumstances disclosed by the evidence—that Dr Blood came in on the case in the emergency, was asked to continue on the case by the employee's father, together with his correspondence, talk and contact with the insurer or its representative,—find that there existed justifiable cause under section 30 for Dr Blood continuing his treatment of the employee as a private patient," was unwarranted in fact and in law. This contention rests upon the fact that the employee was sent to the nearest general public hospital for emergency treatment, which was rendered by a physician on the staff of the hospital called by the hospital authorities, that there is no evidence the treatment began as that of a "private patient", that the treatment continued in the same hospital by the same staff surgeon, and the hospital bills were paid by the insurer. As contended, the treatment did not begin as that of a "private patient," but it was continued as such following the employment of Dr Blood at noon on the day of the accident. The insurer relies on Allen's Case, 265 Mass 490. That case is distinguishable in its facts from the instant case in two respects (1) the employee did not select the physician, and (2) there was no emergency or other justifiable cause which gave a right of recovery to the physician for services rendered. *In the case at bar there were both an emergency and a selection of a physician after the employee had recovered consciousness, the exact moment of such selection being immaterial.*

Decree affirmed

E Field, (R. H Field with him,) for the insurer
W C Crosley, for the claimant

Messrs Cenedella, Gleason, Clark and Mrs Tousant—
for physician.

Affirmed by Supreme Judicial Court.

Opinion filed March 27, 1935

DECREE OF THE SUPREME JUDICIAL COURT

CARROLL, J. In this proceeding under the workmen's compensation statute Dr Spellman, a member of the staff of the hospital to which the employee was taken following his injury, seeks to recover compensation for his services as a physician in the treatment of the employee at the hospital. The employee was paid the compensation due him under the statute and the insurer paid the hospital bill amounting to \$63.00.

The Industrial Accident Board found that the injured employee consulted a doctor, who bandaged his hand, that he then went to St Elizabeth's Hospital where a nurse asked him if he had a doctor, and he said he knew no doctor at the hospital, that the nurse "suggested the name of Dr Spellman and he said that Dr Spellman would be all right." The board further found that the employee did not choose a physician as the statute con-

templated that the insurer fulfilled the obligation placed upon it by the statute and furnished adequate and reasonable hospital services to the employee and denied the claim of the physician for services in the care of the employee. In the Superior Court a decree was entered for Dr. Spellman in the sum of \$45. The insurer appealed.

G. L. c. 152 § 30 so far as material provides that during the first two weeks after the injury the insurer is to furnish adequate and reasonable medical and hospital services that the employee may select his own physician or in case of emergency a physician other than the one provided may be called to treat the patient at the expense of the insurer subject to the approval of the department. As we construe the findings of the Board the insurer complied with the statute and did all that was required of it—it furnished the employee with adequate and reasonable medical and hospital services. Physicians as well as nurses are generally expected to be in attendance at a public hospital. A patient who has been taken to such an institution if he has no physician of his own to treat him naturally expects that he will receive treatment from someone on the staff. When an injured employee under the compensation act goes to such a hospital and does not select a physician the payment to the hospital of its charges includes the expenses of nurses and physicians and the insurer is not required to pay the physician who is a member of the staff for his services.

The Board found as a fact that the employee did not choose a physician. The finding was warranted. The employee was at the hospital for treatment. His response to the nurse's suggestion concerning Dr. Spellman was not a selection of a physician under the statute. The employee was willing to accept such facilities as were offered including nurses and physicians. He accepted the suggestion of the nurse but did not make such a selection as the statute contemplates when a patient selects a physician other than the one provided by the insurer.

There was no emergency which entitled the doctor to compensation under the statute. In case of an emergency a doctor called to treat a patient may recover compensation but this is subject to the approval of the department and in the case at bar there was no such approval.

Decree reversed.

Opinion filed January 4, 1929. Decree to be entered for the insurer.

IDENTIFICATION OF CRIMINALS

According to current reports Dr. Carleton Simon, former Deputy Police Commissioner of New York City in association with Dr. Isador Goldstein, ophthalmologist at Mount Sinai Hospital, New York, has after a year's study of the method of measuring the network of structures in the retina of the human eye devised a system which supplants other methods of identification.

Criminologists have found that chemicals and

surgery may invalidate fingerprints and physical peculiarities of suspects as has been found in some important cases.

The Simon method employs a retinal camera which records the distances of branching blood vessels from the optic nerve through a meshed screen.

It is claimed that anyone can learn how to use the system in two hours and that medical knowledge is not required.

The destruction of finger marks and hemishes has aided criminals in several cases. Enemies of society will not be likely to have their eyes removed.

THE REGISTRATION OF OSTEOPATHS IN GREAT BRITAIN

The Committee of the House of Lords (England) has recommended that the bill for the registration of osteopaths be not further proceeded with.

This action is the result of an intimation by the supporters of the measure that the bill if enacted would place osteopaths on a par with doctors and also because further consideration be given to the scientific basis of osteopathy.

The Committee also reported that "no definition of osteopathy had emerged which satisfactorily differentiated the osteopathic sphere of activity."

There are reported to be from two thousand to three thousand osteopathic practitioners in Britain of whom only about one hundred and seventy can claim to be qualified.—Digest of a report in the *New York Times* July 21, 1925.

NOTICES

REMOVAL

HAROLD BEECHER HARRIS, M.D., announces the removal of his office to 465 Columbus Road, Dorchester, Massachusetts.

LAWRENCE CANCER CLINIC

Established 1928

Lawrence, Mass.

July 20, 1935

To the Physicians of the North Half of Essex County

Dear Doctor

The regular Lawrence Cancer Clinic to be held at Lawrence General Hospital, 1 Garden Street, Lawrence, upon Tuesday, August 6, at 10:00 A.M., will be a Demonstration Clinic with Channing C. Simmons, M.D., of Boston, Surgeon-in-Chief to the Collis P. Huntington Memorial Hospital and member of the Cancer Commission of Harvard University, Boston, present as consultant. You are invited to accompany any of your patients whom you desire shall have this service, or to send them with a note and a report will be returned to you. This

service is gratis Your attendance at the Clinic is always welcome

This Clinic is endorsed by the Committee on Postgraduate Instruction of the Massachusetts Medical Society

ELEVENTH CLINICAL CONGRESS OF THE CONNECTICUT STATE MEDICAL SOCIETY

NEW HAVEN, SEPTEMBER 17, 18, 19, 1935

The registration fee for the 1935 Clinical Congress will be \$2.00 Luncheons are not included in this fee, but will be available at a low cost.

More than 600 physicians from 9 states attended the 1934 Clinical Congress

To increase the value of the Congress, a Commercial Exhibit of some 25 carefully chosen exhibitors has been added this year The Exhibit will be held in the new Tompkins East I of the New Haven Hospital and will be open throughout the Congress

Afternoon sessions each day will be devoted to demonstrations and round table discussions on the subjects that have been presented at the morning sessions

All papers presented before the Congress will be abstracted in the October issue of the *Yale Journal of Biology and Medicine*

Free parking of automobiles for members of the Congress will be available near the meeting place Continuous telephone service will be maintained so that members can be reached at any time by calling New Haven 51161, Clinical Congress extension

Early registration will facilitate the work of the Committee on Arrangements If you expect to attend the congress, please send your check for \$2.00, made payable to the Connecticut Clinical Congress Names and addresses of all who register before

August 25 will be published in the final program to be distributed about September 1 Complete program may be secured by addressing

Creighton Barker, M D

Chairman of the Committee on Publicity
and Registration

129 Whitney Avenue, New Haven, Connecticut

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING MONDAY, AUGUST 5, 1935

Wednesday, August 7—

BOOK REVIEW

The Modern Method of Birth Control Thurston S Welton 168 pp New York Walter J Black, Inc \$3.00

This little book gives a clear explanation of the modern concept of the physiology of reproduction It is, however, merely another paraphrasing of the work previously published by Ogino and Knaus It does not differ essentially from Lutz's book "The Rhythm" except in the use of a series of diagrammatic charts, of which there are sixty-seven, together with a celluloid calendar wheel to be used with them Actually there are only seventy-four pages of text in addition to the short explanations that go with the charts To your reviewer the use of these charts seems to add an unnecessary complexity to what is probably going to be a very satisfactory method of birth control As has been said, in reviewing other books on this same subject, to date we lack sufficient information to give this advice in cases of serious illness Another objection to this book is its price Three dollars seems a rather large amount for the information given

NUMBER 6

ON PERFORATING INFLAMMATION OF THE VERMIFORM APPENDIX WITH SPECIAL REFERENCE TO ITS EARLY DIAGNOSIS AND TREATMENT*

BY REGINALD FITZ, M.D.†

THE history of appendicitis is of especial interest to all physicians of Massachusetts. At the first meeting of the Association of American Physicians on the 18th of June, 1886, R. H. Fitz, a Bostonian, the Shattuck Professor of Pathological Anatomy in Harvard University read a paper entitled "Perforating Inflammation of the Vermiform Appendix with Special Reference to its Early Diagnosis and Treatment." This paper was discussed at length by

ures reflect very fairly the attitude of the entire medical profession toward appendicitis. At most universally appendicitis has come to be regarded as a surgical ailment, a disease taught by surgeons to medical students and practitioners. It is a bold medical man who raises his head in public and claims more than a bowing acquaintance with disorders of the *appendix vermicularis*.

It is not to be wondered at that the disease at first appeared of so great surgical interest. For eventually, the treatment is apt to be surgical rather than medical in nature. Naturally, therefore, surgeons have done most of the observing, writing and talking about the diagnosis and treatment of appendicitis, its opera-

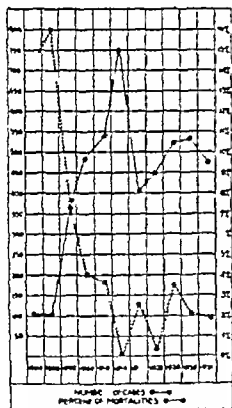

FIGURE 1. Appendicitis in the Massachusetts General Hospital.

William Pepper of Philadelphia, E. G. Janeway of New York, and by several others of the members present, and may fairly be said to mark the beginning of the general clinical recognition of the disease in this country.

Described first by a pathologist at a meeting of physicians, the disease soon was claimed by the surgeons. In the past fifty years but five papers on the subject of appendicitis have been presented at meetings of the Association of American Physicians, whereas in the same period of time approximately ten times as many papers on this topic have been read at the meetings of the American Surgical Society. These fig-

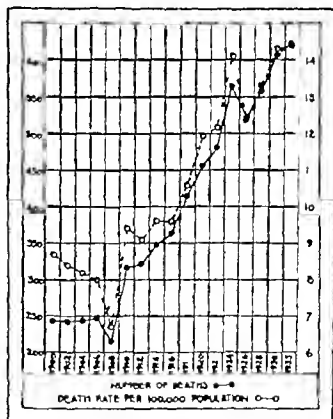

FIGURE 2. Appendicitis as an increasing Health Hazard. (From the Vital Statistics of Massachusetts.)

tive technique, and postoperative complications and, in fact, have done all in their power to make appendicitis as safe a disease as possible. They have accomplished a great deal. The records of the Massachusetts General Hospital serve well to illustrate what has taken place all over the country.

In the early days when the diagnosis of appendicitis seemed relatively difficult, but few cases were operated on and their mortality was high. Little by little the surgeons grew famil-

*Presented at the Fiftieth Meeting of the Association of American Physicians, Atlantic City, May 1, 1935.
†Fitz, Reginald—Physician to the Peter Bent Brigham Hospital, Boston. For record and address of author see "This Week's Issue," page 280.

lar with the disease, operated earlier and with increasing temerity and thus succeeded in reducing to a very low figure the operative mortality in any large group of cases

During these years of improving surgical technique, however, a peculiar phenomenon has taken place. The total number of deaths from appendicitis has steadily increased. Each community with a collection of vital statistics duplicates the curious figures which have been observed in Massachusetts.

Here, for example, the death rate from appendicitis has increased from 8.7 per 100,000 population in 1900 to 14.4 in 1933. In 1900 only 243 fatal cases of appendicitis were recorded, in 1932 there were six hundred and twenty-three. Automobile accidents and appendicitis as unnecessary causes of death appear nowadays to loom very large.

It is well known that medical progress advances by cycles. The appendicitis cycle, it seems to me, began at the first meeting of the American Association of Physicians, rotated at once from the pathologist through the hands of medical men to the surgeons who developed satisfactory operative treatment most skillfully, and now at the end of fifty years revolves again to the pathologist and internist in the paradoxical condition I have mentioned, a common disease of low operative mortality in the hands of competent surgeons but in spite of this each year steadily proving fatal to an increasing number of people. During the next fifty-year cycle can pathologists and medical men add anything to the prophylaxis or treatment of appendicitis by which this disease may be jugulated?

Fitz pointed out in his original description of appendicitis that the disease occurred most frequently among healthy young adults, especially males, though it might afflict persons of either sex and any age. The diagnosis, in most cases, was comparatively easy. Sudden severe abdominal pain was the most constant first decided symptom, occasionally accompanied by a chill or nausea and vomiting. The temperature rarely was very high. If general peritonitis developed, it began on the second, third and fourth days after inflammation of the appendix was established. In fatal cases more than two-thirds died during the first eight days of the disease, and two-thirds of these died between the fourth and eighth days inclusive.

If the question of operative treatment arose, such treatment must be applied early. If delay in operation was warranted, this delay must be maintained until abscess formation took place, and then the abscess should be incised as soon as it became evident.

The initial medical treatment, essentially consisted in leaving the patient alone. To keep the bowels quiet was the first and last thought of the physician. Absolute rest in bed, and liquid diet in small quantities often repeated

were indicated, above all, sufficient opium to neutralize pain. A cathartic or laxative might be demanded by the patient or his friends and an enema be thought desirable. It appeared that the stirring up of peristalsis by such means was strongly contraindicated. Such a procedure might be the means of at once exciting a general peritonitis. If operation was decided against and recovery ensued the bowels opened spontaneously a few days after the discontinuance of the opium. Recovery from an attack of acute appendicitis often proceeded quickly, steadily and without disturbance, the appetite and sense of well-being returning long before the bowels were opened.

Such, in brief, were the ideas concerning acute perforative appendicitis in the days when the disease was in its infancy. They were based on sound clinical judgment and common sense and still stand the test of time.

Appendicitis remains much as it was, a disease occurring most frequently among healthy young adults, especially males, though it may afflict a person of either sex and any age. In a series of 2600 cases in adults* treated at the Peter Bent Brigham Hospital sixty-eight per cent occurred in men and thirty-two per cent in women. The age distribution of these cases shows that nearly two-thirds were in people under thirty, and that only six per cent occurred in individuals past fifty.

The overwhelming majority of the Brigham Hospital case reports are to be found in the surgical records. Here appendicitis has been divided into five groups:

APPENDICITIS	CASES	DEATHS	MORTALITY
UNQUALIFIED	64	0	0
CHRONIC	800	1	1%
SUBACUTE	238	1	.4%
ACUTE	947	7	.7%
ACUTE WITH ABSCESS	551	61	11%

FIGURE 3. A classification of appendicitis to illustrate the dangers of the perforated appendix.

This classification merely serves to illustrate what everyone knows: the chief mortality from appendicitis occurs in those cases which have perforated and have developed general peritonitis.

Assuming that the Peter Bent Brigham Hospital's experience with appendicitis is not abnormal, one can estimate in round numbers from its figures and the reported deaths in the State that in 1932 at least 20,000 cases of appendicitis in adults were treated in Massachusetts. This gives some idea of the prevalence of the disease and its importance as a problem in public health.

Another interesting feature is brought forward if one estimates the age group in which

*Since the Peter Bent Brigham Hospital does not treat any significant number of children all cases under ten years of age have been excluded.

occurs the chief mortality from appendicitis. The older the patient with appendicitis, the poorer is the prognosis. This fact is illustrated in graphic form by figure 4. The data support the viewpoint of many clinicians that appendicitis in young people is easily recognized, but that in the elderly it may present a peculiarly baffling diagnostic problem. Frequently this is forgotten.

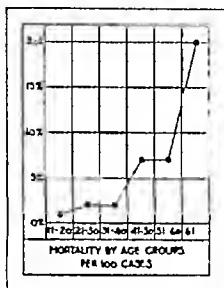

FIGURE 4. A tabulation of fatal cases to illustrate the danger of appendicitis in elderly individuals.

The surgeons, and with much to be said on their side, blame two factors as chiefly responsible for the increasing gravity of appendicitis: they claim that too often the disease is not recognized with sufficient promptness, and that all too often cases are mistreated with laxatives or cathartics. The experience of the Peter Bent Brigham Hospital bears out these claims. Of sixty-five fatal cases of acute perforative appendicitis, but eleven per cent were operated on within twenty-four hours of the onset of acute abdominal pain, and but thirty-seven per cent within the first forty-eight hours. No case was given the benefit of surgery within the first twelve hours. On the other hand, in 100 cases of acute perforative appendicitis which recovered, twenty-five per cent were operated on within twenty-four hours of the onset of acute abdominal pain and fifty-two per cent within the first forty-eight hours. Eight per cent received the benefit of surgery within the first twelve hours of the onset of symptoms. Evidently it is well still to be reminded that if the question of operative treatment arises, such treatment must be applied early to be effectual.

The cathartic situation is equally striking. In sixty-five fatal cases seventy-four per cent had taken some sort of cathartic before entering the hospital, while in a hundred cases that recovered only fifty-one per cent had taken a laxative. Of the fatal cases thirty-one per cent had utilized multiple laxatives like salts, enemas, and castor oil combined and often repeated, whereas in the recovering group only thirteen per cent had employed such drastic treatment. Surely in the early management of appendicitis, to keep

the bowels quiet should still be the first and last thought of the physicians.

These remarks, admittedly, are trite and bring out nothing new or original. Every doctor recognizes that appendicitis is a common disease, more serious in elderly people than in the young, that it must be treated early by surgery or else left to recover spontaneously, and that laxatives are likely to be injurious. But in spite of this general knowledge, the deaths from the disease continue to climb each year. I raise the question as to whether concerted action on the part of the medical profession to combat appendicitis is not indicated. Such an effort has been attempted locally with some success in Philadelphia under the stimulus of Dr. John O. Bower. Similar efforts might well be made in other parts of the country.

There are at least three logical lines of attack on a public health problem of this nature. The first is in our Medical Schools. Appendicitis should be taught as a medical disease, more stress should be laid on the fact that it is the family doctor who almost invariably is called in to make the diagnosis and instigate treatment. Men going into practice must be taught more of the life history of appendicitis, of its diagnosis of its initial medical treatment of its dangers. In brief, more responsibility must be placed on the shoulders of the general practitioner for the early recognition and treatment of this disease.

Secondly, local medical societies must maintain a constant interest in appendicitis. Most doctors learn by repetition. The story of appendicitis must be repeated over and over to men in general practice and it apparently cannot be too strongly emphasized that appendicitis as a rule is an easy disease to recognize, that it begins with abdominal pain and usually with very slight fever, that almost any acute attack of painful indigestion is likely to be an early symptom of appendicitis, that stomach aches must always be taken seriously and not be treated over the telephone, that laxatives of any sort are always contraindicated and that the proper time to remove the acutely inflamed appendix is as early as possible after the diagnosis is established.

Thirdly, and perhaps nowadays this is of most importance, a campaign of popular education must be instituted. The public at large appears eager to learn about disease. Certainly those who "tune in" on their radios each evening are learning the names and uses of several laxative drugs which can be readily purchased at almost any drug store to be taken in case of need. Medical authorities who arrange programs for laymen appear to be too little interested in the increasing importance of the appendix problem and should do something to combat laxative propaganda. If men, women and children can be taught to respect their intestines

and to abandon the habit of using cathartics on the least provocation, many unnecessary deaths from appendicitis will be prevented

Appendicitis, as its recognized fiftieth birthday approaches, remains a peculiar disease. Its surgical treatment on the whole is satisfactory. Its medical treatment, simple as it is before the

surgeon sees the patient, has fallen into desuetude. May appropriate action be taken by medical men within the next fifty years to relegate appendicitis to the rank where it belongs, a disease easily diagnosed, of no great danger, and when recognized early and submitted to proper treatment, readily amenable to cure!

VISUAL DISTURBANCES WITH DIGITALIS MEDICATION*

BY WILLIAM H. ROBEY, M.D.†

DIGITALIS or foxglove as used in medical practice is the dried leaves of *Digitalis purpurea*. It grows wild in Europe, Australia and Oregon and is cultivated in the United States, England and Germany. It may be seen as a beautiful, blue-flowered plant in New England gardens. It was named by Linnaeus because of its finger-shaped corolla. More has been written about digitalis than almost any other drug. Withering, who first noted the benefits of digitalis effusion upon edematous patients, supposed it was a diuretic and did not realize that the action of the drug caused a slowed and strengthened ventricle which was sending more blood through the kidneys. The writer worked in his early days with the instructor in therapeutics at the Harvard Medical School who always gave his cardiac patients the tincture of digitalis but used the effusion if there was edema. More than a hundred years after the time of Withering there were many discussions continuing up to my student days upon the effects of digitalis on the cardiac muscle and the kidney. Many fears gripped physicians concerning its use, one of the most fixed being its supposed cumulative action. This belief was strong up to thirty-five years ago and while there is an accumulative effect, as has been amply proved, it need not occur with harmful results if the physician has the cardiac case under ordinary observation. As a matter of fact, in the old days so little digitalis was given a patient in each twenty-four hours and often the preparation was so nearly impotent that it made little difference. To-day, thanks to the physicians (J. H. Pratt and others) who have shown pharmaceutical concerns and dispensing druggists how to make potent preparations, we have an active drug competent to produce results. The dose has been standardized and if carefully weighed amounts of the leaves are given in tablet or pill form the physician can regulate the daily intake with reasonable accuracy even in office and ambulatory patients. The drop dose is much more inaccurate and at the Bellevue Hospital in New York a large number of glass droppers have been collected showing the great variation in the size of the drops and

therefore the difference in amounts of digitalis in single doses. The writer has not used liquid preparations of digitalis in the last fifteen years for this reason. We have worried through the anxiety over frog and cat units but since reliable pharmaceutical houses have learned how to dispense carefully weighed and properly aged and dried leaves we no longer feel the necessity of hurrying to a laboratory with the digitalis purpurea. We have decided to employ in our practice. Furthermore, if the physician has selected a preparation which has proved efficacious it is useless to keep moving from one to another. In my early years as a teacher, I found many graduates who resorted to digitalis upon the slightest suspicion of what they considered a cardiac abnormality. The discovery of a simple systolic murmur in an otherwise perfectly functioning heart was sufficient for its use. To them a systolic murmur seemed to indicate something wrong and something wrong required digitalis. As a student I was taught not to give digitalis in mitral stenosis because the drug was supposed to slow an already overloaded left auricle and delayed still more the passage of blood through a narrowed mitral valve. It was adding insult to injury, again, we were cautioned about the use of digitalis in aortic regurgitation because an overworked left ventricle might be stopped during diastole but we gave it in heart block and coronary thrombosis and all this was because we did not understand the effects of the drug upon various circulatory structures. It was not until laboratory experiments upon animals showed that digitalis exerts its influence principally upon the conducting tissues of the heart that we began to use it intelligently.

Digitalization is produced by an amount of the drug which in twenty-four to seventy-two hours will achieve the desired effects upon cardiac rate and the general circulation. The drug when necessary may be given at the rate of one gram for every ten pounds of body weight but in many cases one-half this or about four and one-half to six grains in twenty-four hours will produce the results in one or two days after which a maintenance dose must be given. This maintenance dose is very important and can be continued for several months or even years in selected cases. Formerly the mistake of not giving a maintenance dose was not appreciated

*Presented before the Dorchester Medical Club, March 14, 1935.

†Robey, William H.—Clinical Professor of Medicine, Emeritus, Harvard University. For record and address of author see This Week's Issue, page 250.

or there was the fear of a cumulative effect and the results of digitalization were lost.

The difference between "digitalization" and "toxic effects" must be appreciated. They are sometimes thought to be the same but they are not. Digitalization may be obtained in many persons without toxic effects while, in some, toxic effects may be produced by small doses before digitalization has been secured. At any stage in the process of digitalization the onset of toxic symptoms is the indication for a cessation of the drug. It seems to make little difference how the drug is administered and it is undecided whether the untoward effects are a reflex from the heart or emanate from the medulla.

The unpleasant symptoms of digitalis are well known to clinicians. In some patients a certain amount of digitalis often not enough for digitalization, whether in one dose or repeated doses, causes nausea or vomiting. It must be remembered, however, that in heart disease the almost constant nausea may not be due to digitalis and mouth doses may be discontinued and some other method such as intramuscular or rectal administration may be tried.

There are certain well known indications for the discontinuance of digitalis such as nausea, vomiting and occasionally diarrhea, a cardiac rate below sixty or a sudden slowing of the rate, the onset of extrasystoles or coupled beats, the change of regular rhythm to arrhythmia, complaint of headache, dizziness or disturbed vision.

The object of this paper is to report two cases of disturbed vision occurring without other symptoms of toxicity.

CASE I. A physician sixty-two years old came to my office on November 8, 1925 because of an attack of paroxysmal tachycardia one week before. His childhood history was not remarkable. Between the ages of twenty-five and thirty he had an acute tonsillitis each winter but none since. At thirty-two he fell on some slippery steps and the physician who examined him thought because of pain in the precordial region that he had either "endocarditis" or "pericarditis." About this time he applied for life insurance but the examiner declined to accept him. He could not remember having been ill in thirty years except for a mild attack of influenza in 1910. He considered his general condition good enough for his age and usual activities and would not have thought of consulting a physician if he had not had the tachycardia. He had always had a quiet rather comfortable mode of life with a small practice visiting his patients by walking or using street cars. His general strength was good, he always slept well and his digestion was satisfactory. Nocturia occurred once usually between 4 and 5 in the morning. There was no breathlessness at any time except after climbing three flights of stairs, no head ache, edema nor any precordial nor allied pain even with exertion. When not having an attack of tachycardia he was unconscious of his heart action except for an occasional premature contraction which he considered compatible with his age.

On November 1, 1925 he had a sudden attack of rapid heart action unaccompanied by pain or

dyspnea which lasted five minutes and ceased as suddenly as it had begun. He had not hurried before the attack and had been as comfortable as ever. Two days later while reading the paper after breakfast he had a similar attack and on the evening of November 7 one which lasted an hour and ended suddenly.

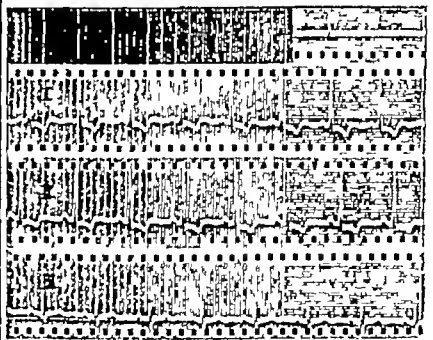

The physical examination was not remarkable. The heart by fluoroscope showed a moderate enlargement to the left; the rate was sixty-eight and regular. The pulse was synchronous with the heart.

M T T No. 1 November 1, 1925. Note the high takeoff of QRS and the marked downward deflection of T₁ and T₂.

and the radials somewhat atheromatous. A blowing systolic murmur was heard over the precordia. The blood pressure was 135/90. The lungs were clear. The liver was slightly palpable but otherwise the abdomen was normal. The leg vessels showed some sclerosis but were without circulatory symptoms.

In view of the physical findings a diagnosis of arteriosclerosis and coronary sclerosis was made. Paroxysmal tachycardia in this patient was in the

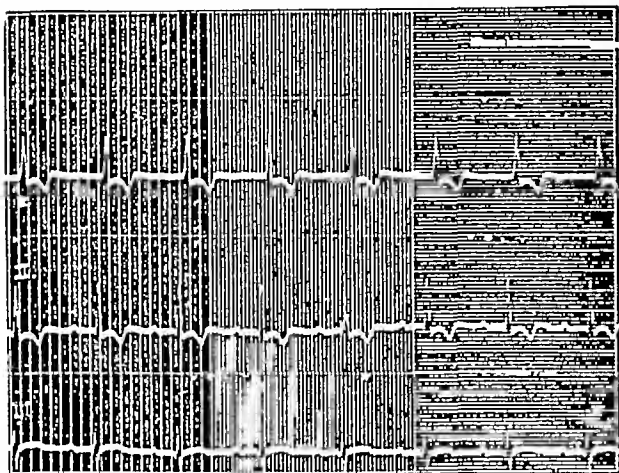

M T T May 27, 1929

same class with angina pectoris or nocturnal breathlessness. No drugs were prescribed at this visit but attention was given to diet and habit of living. He returned on May 27, 1929 with the statement that he had been quite free of cardiac symptoms since his visit in November but recently the tachycardia had recurred with greater frequency occasionally there was a sense of fullness in the neck but it was not like the nuchal compression of which angina pec-

toris patients complain. Breathlessness did not occur with the tachycardia but came only on climbing three flights of stairs. On the other hand such exercise did not produce tachycardia nor precordial distress but once when romping with his young son he had an attack of tachycardia but no angina pectoris. The rate was seventy two, the rhythm regular and the blowing systolic murmur was heard as at the previous visit.

Digitalis was prescribed, gr jss three times daily and a tablet of nitroglycerine gr 1/100 to be used at the onset of tachycardia. He came again on June 26, 1929 with the statement that he had been entirely free of tachycardia and had felt about as well as usual. He discontinued the digitalis after taking it for two weeks because of a visual abnormality

M T T November 13 1931 Note the slowing of conduction in the P-R interval and the slurring of the R waves.

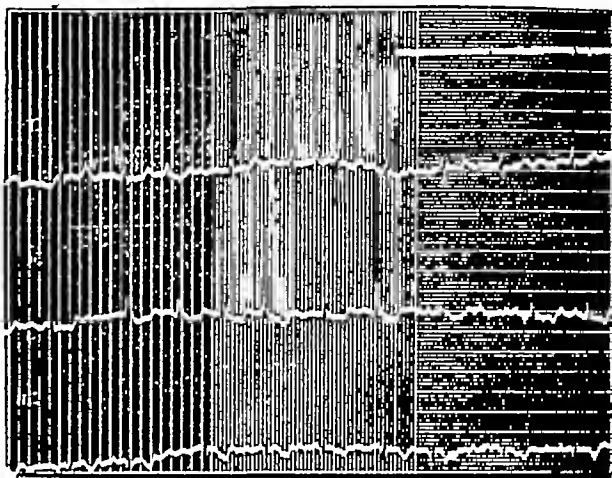

which he thought might be due to the drug. When ever he looked at a distant object it appeared to be dazzling white. This was not preceded by green or yellow vision. Red brick buildings across the street lost their red color and became a brilliant white. After cessation of the digitalis for a week normal vision returned. There were never any gastrointestinal symptoms. I telephoned to him several times during the succeeding months but he reported that he was comfortable except for an occasional brief attack of tachycardia.

On May 7, 1930 he reported that he had had an attack of tachycardia which started at 1 A M and lasted until 4 A M. Digitalis gr j was again tried but white vision appeared after a few doses. On June 11, 1930 he stated that he had a tenderness near the cardiac impulse area with a little continuous pain which was only slightly relieved by nitroglycerine. Auricular fibrillation appeared about September 11, 1930 and digitalis was given, gr j, five times daily but had to be discontinued because of the distressing white vision, however the rhythm soon became regular. He continued quite comfortably until the summer of 1931 when he suffered from attacks of paroxysmal dyspnea even when at rest. From then until September 1932 he had occasional attacks of paroxysmal tachycardia and dyspnea when he died in a few days of general cardiac and circulatory failure. At all times he was relieved by small doses of digitalis which were discontinued as soon as the vision became disturbed. It is interesting to note that while his electrocardiograms were similar to those of other patients having angina pectoris he was almost entirely free from this distressing symptom. Undoubtedly his death was due to painless coronary occlusion. If

one reviews his history and physical signs one sees the succession of cardiac events which often end in occlusion.

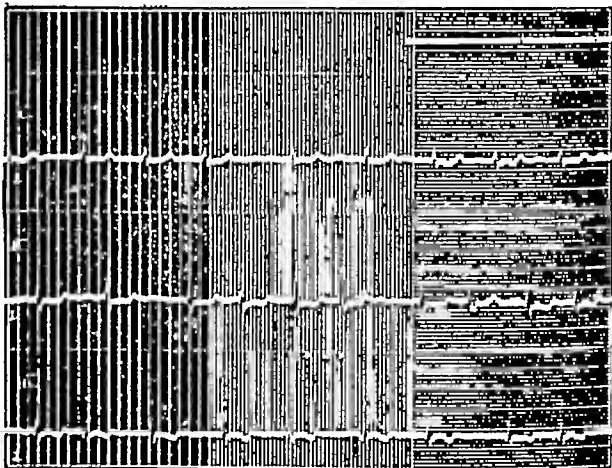

The second case illustrates the visual changes produced by digitalis with a slight difference in manifestation.

H F L aged thirty nine, married, having a healthy husband and two daughters. She was first seen on February 20, 1933 with her physician. The family

H F L June 22 1934 Auricular fibrillation.

history was unimportant. In her youth she had been singularly free of the infectious diseases. There was never a recognized attack of rheumatic fever but she had tonsillitis at fifteen years of age and in the same year an attack of chorea. At the age of twenty four a physician discovered signs of

H F L November 2 1934 Improvement in auricular fibrillation even with small doses of digitalis.

a cardiac valvular lesion. For the last twelve years she has been conscious of cardiac disturbances and the year before I saw her she had spent two months in bed and later another month.

She did not have headache but occasionally suffered from vertigo if the heart was irregular. There was breathlessness on exertion.

She was healthy in appearance. The heart showed a mitral presystolic murmur with heaving impulse and a rate of seventy-six. The pulse was of small volume but fair quality and the blood pressure 100/80.

On June 22 1934 she came to the office and was found to be in auricular fibrillation with some dyspnea. Digitalis gr Jas was prescribed to be taken at bedtime. The drug was used regularly until July 1 when it was discontinued because of a flashing white light which she said was very much like pulling a window shade up and down rapidly on a bright, sunlit day or sometimes as though the eyelids were closed and opened with great rapidity. Two days after the digitalis was discontinued the white light ceased. She never had green nor yellow vision. When we discussed the symptoms she said that it had occurred once before I saw her when she took digitalis near and far vision were equally affected. During the last twelve months the patient has been very well. She has a very slight auricular fibrillation and her heart has been well controlled by taking digitalis gr Jas daily for four days and then omitting it for a similar period.

The visual disturbances are usually so marked

that it is necessary to discontinue the digitalis. In our two cases enough digitalis could be taken prior to the onset of white vision to produce a considerable effect upon the heart and that effect could be maintained by small doses taken and omitted for similar periods of time. If one finds that complete idiosyncrasy exists then of course may be had to other members of the digitalis group but most of them have been shown to be of small value and to produce toxic symptoms easily. Strophanthus should be tried if digitalis must be discontinued. The other members of the group may have the same effect as digitalis but they are more uncertain. The toxic symptoms of digitalis are probably induced by action of the drug upon the autonomic or involuntary nervous system.

THE NATURAL HISTORY OF SOME RENAL TUMORS*

BY E. ROSS MINTZ, M.D.†

It is not uncommon to find in the literature cases of patients who had renal neoplasms and who complained of intermittent hematuria over periods of five, ten, fifteen, twenty and in some instances, twenty five years. However the literature contains relatively few reports of nephrectomies for renal carcinomata where a definite diagnosis was made of the lesion five or ten years previously, either by pyelograms, the palpation of the tumor mass by exploration or by biopsy of a metastatic process. Four such cases form the basis of this report. They truly show the natural history of the disease in some renal tumors when left to itself and not interfered with by surgery or physical agents.

CASE 1

C. E. S. (Massachusetts General Hospital No 309915) a native white married male thirty seven years of age was admitted to the Urological Out Patient Department of the Massachusetts General Hospital for the first time in 1920 complaining of intermittent hematuria of one month's duration. Cystoscopy at that time showed a normal appearing bladder and a bloody jet coming from the right ureter. The kidney on that side was not palpable and no costovertebral tenderness was elicited. A right pyelogram was made the report of which is as follows: "Kidney appears large on this side and the calices very deep. It is apparently low in position. The middle calyx appears to be of unusual shape. There is a small area of increased density near the tip of the twelfth rib which may be a stone. There is another small faint shadow low down in the kidney about 3 cm from the shadow of the eleventh rib which may be a small particle of dense material in the kidney." The patient was asked to return for further study but did not.

From the Urological Service of the Massachusetts General Hospital.

†Mintz, E. Ross—Assistant Urologist, Massachusetts General Hospital. For record and address of author see "This Week Issue" page 230.

do so. In September 1930 ten years later the patient reentered the Out Patient Department complaining of right lower quadrant pain. He had had several attacks of pain recently but was perfectly asymptomatic for almost ten years. A week before the second entry the patient noticed some blood in the urine. This lasted for two days finally clearing but reappearing again the day of entry to the hospital. There was no history of burning on urination diurnal frequency or dysuria. No mass was palpable in the right loin. A flat abdominal plate showed a dense shadow in the region of the pelvis of the right kidney. The kidney outlines were quite distinct. Both appeared large. The five dense shadows scattered throughout the kidney might be due to localized areas of calcification. Cystoscopy was done and a right pyelogram was made. The bladder appeared normal. The report of the right pyelogram was as follows: "The smaller shadows are arranged in a rounded mass at the lateral margin of the renal pelvis. After injection there is a concave defect in the middle calyx of the right kidney." Intravenous pyelography was suggested and done. "The pelvis of the kidneys are well visualized. The pelvis of the right kidney shows an irregular moth-eaten appearance at its edges with one calyx distorted and running down into the lower pole of the kidney. The upper two calices are large also distorted, and appear to run up to the pole of the kidney. The outline of the entire pelvis has a slightly moth-eaten edge and the pelvis is distinctly deformed by a rounded tumor mass having the diameter equal to the width of the kidney and producing a distinct bulge in the outline of the middle portion of the kidney. The tumor mass contains enormous areas of calcification. The pelvis calices and ureter of the left kidney are negative. The findings are suggestive of a tumor mass deforming the pelvis of the right kidney."

The patient was admitted to the House for operation. Physical examination was essentially negative. The urine was loaded with red blood corpuscles and numerous white blood corpuscles. The Hinton test was negative. The blood non-protein nitrogen was 37 mgs/100. X-ray of the

chest was negative (There was no history suggestive of pulmonary tuberculosis)

OPERATION—(November 11, 1930) J D Barney and E Ross Mintz Ether

Through the regular oblique right loin incision the kidney was exposed. A soft, circumscribed mass the size of a golf ball was noted near the upper pole. It was definitely encapsulated and no invasion of the perirenal fat or renal pedicle was present. The kidney was removed.

Four weeks later the patient was discharged from the hospital after an uneventful convalescence.

PATHOLOGICAL REPORT—(30 2829)

The specimen consists of a kidney twelve by six by four cm. There is a lobulated round soft mass about four cm in diameter over one pole of the kidney. There is a small cortical cyst near the other pole which contains clear colorless, thin fluid. The cut surface shows

Photograph of the kidney removed in Case 1—Adenocarcinoma

a round, red, soft mass about four cm in diameter near the superior pole. It is definitely encapsulated, the wall of the capsule being formed by a dilated, thinned out calyx. At the constricted neck of the above calyx a small mulberry like, elongated calculus protruded into the pelvis. There are small, fine, calcified areas within the tumor mass. The rest of the kidney is normal.

Microscopic Examination shows an adenocarcinoma composed of poorly differentiated pale, vesicular cells with marked papillary formation. Many areas show definite tubular arrangement of the cells. Mitoses are moderate in amount.

Anatomic Diagnosis Renal cell adenocarcinoma

FOLLOW UP

The patient has been followed for four years. X-rays of the chest and spine fail to show any evidence of metastases. His health is excellent and he has no complaints.

CASE 2

F H H, a white native, married, prison officer, aged fifty three, entered the Urological Out Patient Department of the Massachusetts General Hospital May 3, 1924, complaining of hematuria and left loin pain of three days' duration. Five months ago the patient was seized with a dull pain across the lumbar region which lasted for two weeks. He attributed this to a "cold in his kidneys." Three days ago at three o'clock in the afternoon he noticed hematuria for the first time. Later in the day he passed a clot six inches long per urethrum. One hour following this he was suddenly seized with a sharp, severe pain in the left lower quadrant which radiated to the small of the back and was accompanied by nausea and vomiting. The pain lasted all night and was not relieved by morphia. The family physician referred him to the hospital.

Physical Examination showed the patient to be well nourished and well developed. There was slight left costovertebral tenderness, but neither kidney was palpable. The abdomen was moderately distended. The urine showed a rare red blood corpuscle and many bacteria. The blood nonprotein nitrogen was 40.5 mgs per 100 cc. Patient had a slight rise in temperature (100°).

A cystoscopy was done May 7, 1924. The bladder appeared normal. Both ureters were easily catheterized. A left pyelogram was made, the report of which is as follows: "Unusual amount of gas in the colon. No shadows suggestive of stones. After the injection of the opaque mixture the shadow of the pelvis and calices on the left is visible. They are distinctly pathologic in appearance. The pelvis itself is small and narrow, calices usually long and deep without the usual cupping. The upper calyx has lost all of its normal appearance" (George W. Holmes).

A plate of the chest and spine was negative for metastases.

Operation was advised but the patient decided against it and went home.

INTERVAL HISTORY—May, 1933

The patient's health was excellent until one and a half years ago. He again had an attack of hematuria but this "passed off in a few days." One week ago he again noticed spontaneous, insidious total hematuria and consulted a surgeon who referred him to the Palmer Memorial Hospital for study. During the patient's entire illness there never has been any dysuria, frequency, weight loss, asthenia, pain, hemoptysis or cough.

On physical examination nothing remarkable was found. The abdomen was a little large without any abdominal tenderness. Neither kidney was palpable but the patient did not relax. Rectal examination showed a smooth, elastic enlarged benign prostate. The urine showed an occasional white blood cell and one or two red blood cells. The blood nonprotein nitrogen was thirty-one mgs per 100 cc. Hinton, Kahn and Wassermann were negative. The red blood count was 5,150,000. The white blood count was 9,200 and the hemoglobin 80 per cent (Taillqvist). The blood smear was essentially negative.

Cystoscopy was performed May 20, 1933 (George Gilbert Smith). The bladder appeared negative. Both ureters were catheterized with ease. A left pyelogram was made which showed a deformed renal pelvis, fairly typical of a renal

neoplasm. Intravenous skiodan failed to be visualized on the left side. The right kidney, pelvis, calices and ureter were normal. The kidney on the left was definitely enlarged.

OPERATION April 22 1933 (George Gilbert Smith and E. Ross Mintz.) Gas and ether.

Through a left oblique incision the kidney was exposed and found to be malignant. The ureter was clamped, cut and tied. The kidney was easily freed, delivered and removed together with the perirenal fat and a portion of the adrenal. There was no evidence of any invasion of the renal pedicle.

The patient made an uneventful recovery and was discharged from the hospital May 8 1933.

PATHOLOGICAL REPORT (18726)

The specimen consists of a kidney weighing 670 grams and measuring sixteen by eleven by twelve cm. Apparently three-fourths of the

Photograph of the kidney removed in Case 1.—Hypernephroma.

mass consists of tumor tissue. It is lobulated, soft, encapsulated, and contains many hemorrhagic necrotic areas. The capsule does not seem to be invaded. The perirenal fat is negative.

Anatomic Diagnosis—Hypernephroma.

FOLLOW UP

Up to the present time March 1935 the patient is in excellent condition and there is no evidence of any metastases.

CASE 3

F. M. H., a native white married jewel worker aged forty-seven years, was first seen by a Boston surgeon January 1928 for bleeding from the rectum. Examination revealed an ulcerated new growth on the left lateral and posterior walls of the rectum about three inches above the sphincter. After a thorough negative physical examination a one-stage abdominoperineal operation was performed under spinal anesthesia (August 22 1928). An excerpt from the operation sheet follows: "In what was taken to be the right kidney there was a definite dense tumor occupying the region of the pelvis and which suggested either a dense hydronephrosis or a cyst. The kidney itself was movable. The tumor did not feel like malignant disease."

The patient had an exceedingly uneventful convalescence and was discharged twenty-one days after operation. Microscopic section of the rectal tumor showed it to be a well-differentiated adenocarcinoma.

The patient was followed in the Out Patient Department at intervals of six months to a year and at no time were any urinary symptoms present or any abdominal mass palpated. The colostomy worked well and the patient gained rapidly. On January 8 1934 almost five and a half years following his operation, the patient noticed that his urine was dark red. No other symptoms were complained of. Examination of the urinary sediment showed many red blood cells. The abdomen was negative. Cystoscopy was done two days later and showed an essentially normal bladder. Intravenous injection of skiodan showed the left kidney, pelvis, calices and ureter to be well visualized and normal in appearance. On the right side only a deformed upper calyx was shown. The lower calices were not visualized. The shadow of the right kidney appeared quite large. The enlargement appeared chiefly in the upper pole. A diagnosis of renal neoplasm was made. A plate of the chest and spine was negative for metastases. The patient went home to get his affairs in order.

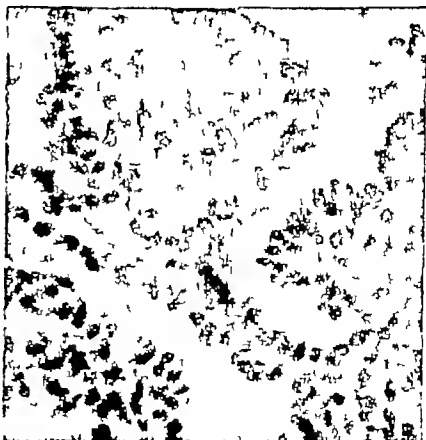

OPERATION Gase and oxygen April 21 1934 (George Gilbert Smith and E. Ross Mintz.)

Through a right oblique incision the kidney was exposed. The twelfth rib was resected. The lower half of the kidney was the site of a round rather firm smooth tumor five inches in diameter. The fatty capsule and the pedicle were apparently not invaded. The kidney together with all the perirenal fat was removed.

The patient was discharged from the hospital after an uneventful postoperative course.

PATHOLOGIC REPORT — (1566)

Specimen consists of a right kidney weighing 350 grams. There is a rather firm round tumor

High power micro-photograph of kidney removed in Case 3.—Adenocarcinoma.

measuring eight by eight by seven cm. at the lower pole of the kidney. On section it is moderately firm and well encapsulated. The pelvis is slightly dilated. The renal vein is not invaded.

Microscopic section of the tumor shows it to be an adenocarcinoma.

FOLLOW-UP

The patient has been followed and up to the present time there is no evidence of a metastasis. The chest and spine are negative for metastases by x-ray examination.

CASE 4

F L M A white, native, married male, aged fifty-nine, entered the Massachusetts General Hospital Urological Out-Patient Department May 13, 1924, complaining of severe and distressing pain over the sternum.

Approximately twenty eight months ago the patient was seized with a severe pain over the sternum after a very vigorous sneeze. This forced him to stop in his tracks and hold his breath. In a few minutes the pain disappeared and for two months he was symptom free. At that time "influenza" confined him to bed. Following this malady his wife noticed a small lump over the midsternum the size of a walnut. This is the site of the present lesion. The mass was neither hard nor noticeably soft, non pulsatile and the overlying skin was normal. The "lump" grew slowly but steadily until two years ago it reached the size of a "good sized peach". The patient consulted his doctor who referred him to a specialist for luetic treatment. Treatment was given for two and a half months, following which the patient's face became edematous. Therapy was then stopped.

During the past year the tumor has not grown perceptibly but it has taken on a definite pulsating character and has caused considerable pain. A vice-like constriction was felt about the growth with each heart beat. This sensation has been constantly present and varies in intensity from time to time. Exertion or any physical movement increases it. Radiation of the pain to both breasts and arms in the region of the biceps muscles occurs at times. The pain not infrequently interferes with the patient's sleep and makes him very introspective and suspicious of his condition. No symptoms referable to the respiratory tract are present.

Physical Examination shows a well developed and well nourished male in no apparent distress. The left pupil is slightly less dilated than the right. Both react normally to light and accommodation. There is a large dome shaped tumor ten by twelve cm over the upper sternum. It is exactly in the midline and covers the area from the insertion of the fourth rib up to the interclavicular notch, and laterally over the costal cartilages on both sides. It pulsates synchronously with the heart beat and transmits a systolic murmur which is propagated along the great vessels to the right side of the neck. This murmur cannot be heard over the heart itself. The diagnosis lay between a pulsating new growth and aneurysm of the aorta. Fluoroscopic examination of the chest showed the aortic arch to be normal in size and shape. No mediastinal tumors were visible. In the lateral view the outline of the sternum is well shown. The bone in the upper portion of the sternum is continuous with the shadow of the tumor. The lesion was interpreted as probably a malignant tumor of the sternum.

OPERATION May 21, 1924 (Drs C A Porter and E P Churchill)

An attempt was made at excision of the pulsating sarcoma and the removal of the entire mass

was considered impossible. A finger inserted behind the sternum failed to reveal an aneurysm. Microscopic section of the tissue removed (24-5-108) showed it to be a metastatic hypernephroma.

Postoperative Course The wound became infected but finally healed. The patient was discharged June 23, 1924. Cystoscopy was decided against as the patient was very suspicious of his condition.

Second Reentry Seventeen months later the patient was admitted for question of an alcoholic injection of the nerves to the tumor, but this idea was given up. In the interval between admissions the patient was given deep x-ray treatments. This seemed to have little effect. At present his strength has returned to to some extent and he is able to be about, exercising moderately and taking long rides in the country. The pain is now described as constant and dull. The tumor mass is the size of half a tennis ball. It is soft, pulsatile and circumscribed. A bruit is heard all over it and for one or two inches around it. The manubrium and upper sternum are apparently invaded and eroded by this tumor. There has been no urinary sign or symptom present. The urinary sediment is negative. The red blood count is 4,888,000 and the hemoglobin 90 per cent. The patient was discharged November 3, 1924.

Third Reentry About four and a half years later the patient was readmitted to the House (May 11, 1929) for one day. He was presented at one of the surgical meetings. For two years after his second discharge from the hospital he felt in "pretty good shape", but for the last two and a half years he has been progressively bothered with low back pain, especially in the region of the left sacroiliac joint and left hip.

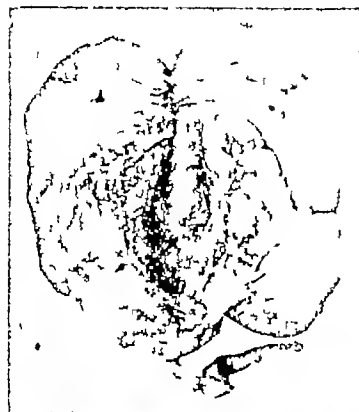

During the past year he has been troubled with difficulty in starting his stream, diurnal frequency, some dribbling and nocturia. Rectal examination revealed a moderate sized, benign, elastic prostate. No residual urine was present. The sternal mass has increased slightly in size. Overlying the left sacroiliac joint there was a roughly rectangular area 10 x 12 cm of telangiectasis. The skin was indurated and there was slight tenderness over this area. Both the sternal mass and the mass in the left lower quadrant gradually increased in size. The patient steadily went downhill and finally died one year later, May 5, 1930.

AUTOPSY—(5830) The body of a well-developed and fairly well nourished man, appearing to be about sixty five years of age. Over the upper portion of the sternum is a large bulging tumor which involves an area of skin eight cm in diameter. A large area of the surrounding skin, approximately twenty cm in diameter, shows a brownish pigment and extremely numerous telangiectases (X-ray Therapy). The left arm and hand show marked pitting edema extending upwards half-way from the elbow to the shoulder.

Intestines A movable, white, firm nodule two mm in diameter is in the mucosa of the jejunum.

Thorax The area underlying the telangiectatic radiated skin shows an extreme fibrosis of the subcutaneous tissues and also a peculiar appearance of the muscles which are unusually pale slightly edematous and, on section, show marked fibrosis extending in a closely visible net-

work between the muscle hundles. A large tumor is found which has completely replaced the manubrium and a small portion of the first and second ribs on each side. No trace of the bones remains in the infiltrated area. The clavicles are uninvolved. The tumor projects anteriorly from the face of the sternum for a distance of about three cm. It also projects posteriorly laterally and in one place superiorly where it

Photograph of autopsy specimen removed in Case 4—hypernephroma.

Sagittal section of sternum removed at autopsy in Case 4 showing the metastatic hypernephromatous mass.

passes up into the tissues of the neck through the sheaths of the right scalene muscles. The superior vena cava and particularly the innominate vein are pressed upon and to some extent surrounded by the tumor mass. On section the tumor consists of white to yellow occasionally orange, soft, very vascular tissue. There are extensive areas of necrosis.

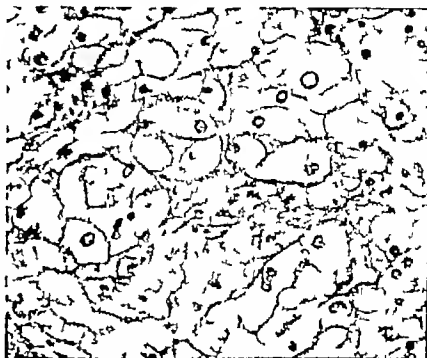

Lungs. Numerous small tumor nodules varying from two to fifteen mm in diameter are scat-

tered irregularly over the pleura and throughout the substance of the lungs. There are also scattered areas of coagulation and of increased consistency typical of bronchopneumonia.

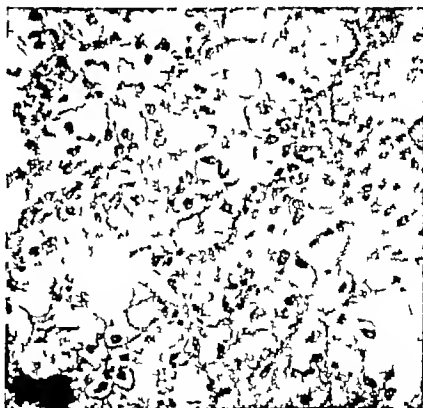

Aorta. Marked atheroma.

Gall Bladder. Mass of stones.

Kidneys. The right kidney is distinctly enlarged and feels cystic on external examination. On section a cyst 8 cm in diameter surrounded

High power micro-photograph of kidney in Case 4 showing the large vacuolated clear cells seen in hypernephroma.

High power micro-photograph of biopsy specimen from sternum in Case 4 removed in 1924.

by a shell of tumor tissue one to two cm. in diameter occupies the central portion of the kidney and projects from its medial aspect. The cavity is filled with thin blood-tinged fluid. The pelvis is distorted and also dilated as it passes anteriorly to the tumor mass. The tumor however does not involve the pelvis at any point. The left kidney is negative.

Pelvis. In the left lower quadrant of the abdomen and on the left side of the true pelvis a large tumor mass can be felt to the retro-

peritoneal tissues. On section it is found to involve the quadratus groups of muscles and also the entire crest of the ileum which shows extensive destruction of the bone and an infiltration with a tumor similar in appearance to that in the sternum.

Tumors. Sections from the primary renal tumors, the pulmonary, sternal and other osseous metastases all show the same structure. The tumor is composed of epithelial cells in alveolar arrangement, a high proportion are vacuolated, some finely, others coarsely. The differentiation is excellent, mitoses are scarce. It is typical of a hypernephroma.

Anatomic Diagnosis. Hypernephroma of the right kidney with pulmonary, sternal and osseous metastases.

Bronchopneumonia

Arteriosclerosis

Benign hyperplasia of the prostate

Cholelithiasis

DISCUSSION

It is not a generally accepted, appreciated and recognized fact that solid epithelial tumors of the kidney may be and sometimes are slow growing. In Cases 1, 2, 3 and 4, the patients went ten, nine, five and a half and eight years respectively after a diagnosis of renal tumor was made or after a secondary metastatic mass was palpated. Usually when patients with renal cancer are seen, the growths are relatively large, large enough to be palpated abdominally or to deform the renal contour and excretory passages by pyelogram. There is no way of knowing in these instances the duration of the pathologic process before it attained a size sufficient to be recognized by pyelogram or on physical examination. Unquestionably many of these tumors remain benign for a long period of time and some even when they do enlarge to a considerable degree and remain so for a long period of time may not give rise to any distinct metastases. Cases 1, 2 and 3 showed no evidence of visceral or osseous metastases or extension to the perirenal fat up to and after nephrectomy.

Rehn¹ called attention to the fact that unoperated hypernephroma frequently metastasizes late, and that on postmortem even though the renal vein and vena cava were found occluded with tumor no metastases could be found. Walters, in a series of forty-one inoperable renal tumors reported seven cases (17 per cent) who lived five years or more. Three lived five years, two eighteen years, and one fifteen years, one is still living and is beyond the five-year period. These patients had x-ray therapy but it is the belief of most urologists today that deep x-ray therapy for hypernephroma or adenocarcinoma has little or no effect. Berg² reported a case of a patient who went ten years after the tumor was palpated during an operation for acute gangrenous cholecystitis. Smith and Shoemaker³ and Bland-Sutton⁴ cite cases where the humerus was

amputated for malignant metastatic disease secondary to a renal neoplasm, and the patients lived five and six years respectively after the amputation. The primary growths in both cases were not removed, the patients refusing another operation. Albrecht⁵ relates an instance of metastasis to the scapula from a renal growth. The secondary process was removed and four years later a nephrectomy was done. The patient was living and well two years and seven months after nephrectomy. Wolcott⁶ describes a case of renal neoplasm found during an exploratory laparotomy. Nephrectomy was not performed and the patient lived six years after the laparotomy. One of the cases under carcinoma of the kidney in the Atlas of Pathological Anatomy⁷, was of a female patient who had a lump in the left groin for seven years. Barney⁸ recently did a nephrectomy for cancer of the kidney on a female patient on whom he made the diagnosis by pyelogram ten years ago. The patient had intermittent hematuria for ten years.

It has been repeatedly stated that adenocarcinoma is more malignant than hypernephroma. This may be so, but so far as I know no conclusive evidence has been brought forth to substantiate this point of view. This question is intimately related to the natural history of renal tumors. If one exactly knew the "dates of birth" of a series of both of these types of tumors, and followed their growth for years, this question would be solved. Until then any statement in regard to their relative malignancy is a mere conjecture. In this small series two were adenocarcinomas and two were hypernephromas.

In Case 4 the patient presented a "lump" over the midsternum as the initial sign. This later assumed a pulsatile character. By and large, a pulsatile mass occurs in aneurysm, hemangio-endothelioma and metastatic processes from renal or thyroid malignancy. Berg² reported a case of a metastatic pulsatile mass low down in the pelvis which was felt on rectal examination and thought to be aneurysm. A small primary lesion was found in the kidney. Pasteur-Vallery-Radot¹⁰ described a case of a pulsatile mass situated at the level of a fracture of the humerus. It was synchronous with the pulse and a systolic blow was heard over it. Many more instances of pulsatile metastatic masses can be given (Diesser¹¹, Taylor¹²). It would be pointless to list them. The fact that hypernephroma can and sometimes does give rise to pulsatile metastasis is significant.

SUMMARY

Four cases of renal cancer are presented that were diagnosed ten, nine, five and a half and eight years previous to nephrectomy or, in one case, previous to autopsy. A pulsatile metastatic process to the sternum was present in one of them.

CONCLUSION

- (1) Some renal cancers are very slow growing tumors
- (2) Renal cancer may be present for years without giving rise to metastases
- (3) Hypernephroma may give rise to pulsatile metastasis

LATENT SYPHILIS

BY EDWARD WINSLOW KARCHER, M.D.*

LATENT syphilis is one of the great problems in syphilology, indeed, in all medicine. Many cases of it that formerly escaped detection are now being found as a result of the development of sensitive flocculation and precipitation tests and the commendable practice of having one or more of them performed routinely as a part of all physical examinations. The general practitioner who discovers a large percentage of these cases, will not find much light on the subject in the books in his library although the matter is adequately covered, to the extent of our present knowledge in the new literature on syphilis written for the specialist. It is my purpose therefore, to discuss latent syphilis, not with the idea of adding to what is already known to the few but in order to disseminate this knowledge more widely among those who only occasionally treat these patients.

In defining our subject we must distinguish between clinical pathologic and serologic latency, remembering that 'latency' is a relative term and that when it occurs during the first four years of the infection it is called "early", thereafter when the patient's natural resistance has become fully established it is "late".

By clinical latency we mean that syphilitic infection is present and frequently may be active though a careful study fails to reveal any evidence of activity. Pathologic, or true latency is a condition in which the spirochetes though present in the various lesions throughout the body are held in a state of absolute inactivity. Because the presence of pathologic latency is impossible to prove during the life of the patient many syphilologists doubt its existence and believe that the course of untreated syphilis is one of slow degeneration. While it is true that many patients, if they live long enough will develop grave lesions in the cardiovascular

or nervous systems, or benign lesions in the skin, mucous membranes, bones, or viscera, we do see many patients who seem to live in perfect harmony with their spirochetes and, except for a probable positive serum reaction show no clinical evidence of infection, and they eventually die from some unrelated cause.

Serologic latency means that the serologic tests on blood and spinal fluid are negative. It is usually accompanied by clinical latency. It must be remembered however, that there is considerable difference in the sensitivity of the various blood tests, and that a blood specimen may be negative by one test and positive by another. This fact has been most noticeable and at times disconcerting at the Massachusetts General Hospital where for a number of years every blood specimen was examined by the Wassermann and the Hinton tests. The latter was found positive in many of the treated cases after years of continued observation and persistently negative blood Wassermann tests and spinal fluid tests. As we had considered these cases as probably cured it is easy to see that "cure" like "latency" is a relative term.

In untreated syphilis the stage of latency follows the spontaneous disappearance of the secondary lesions and is probably due as Kolmer states to a combination of reduction of virulence in the spirochetes and a neutralization of their pathologic activities by cellular and humoral antibodies especially the latter, as anything depressing the tissue immunity and resistance like trauma or intercurrent infection favors renewed activity and the reappearance of lesions which in turn stimulate antibody formation. The lesions again disappear and the state of latency is reestablished. In some patients this appearance of lesions is repeated again and again with their redistribution and with intervals of clinical latency varying from months to many years throughout the remainder of their lives.

Infections relapses as a rule are confined to

*Karcher Edward Winslow—Deceased February 12, 1929
For record and address of author see "This Week" Issue
1929: 20

the first five years, and occur most often during the first two. Their lesions are frequently multiple and are prone to appear in the mouth or on the genitalia, and since they are the cause of more infections than are primary lesions, careful search should be made for them. The distinctive lesions (gummata) which usually occur later are considered allergic reactions. They are not infectious and are single, as a rule. Transmission of syphilis by intercourse during latency must be given consideration, as a number of investigators have found *Spirochaetae pallidae* in the seminal fluid in the absence of any clinically recognizable genital lesions.

One must not infer, however, that because a patient does not develop any clinical signs of relapse that all is well. The true condition is, as Warthin pointed out and as Stokes stressed, that clinical latency is being maintained by antibodies developed in numerous spirochetal foci located in the capillaries of the visceral parenchyma and in the cardiovascular and nervous systems the so-called chronic inflammatory reaction. If enough natural resistance is not developed, or if the patient is insufficiently treated, these small, often microscopic, lesions tend to progress slowly but surely. They may be present for years without causing symptoms and may defy clinical recognition. Eventually, however, in many cases they produce serious lesions: hepatic cirrhosis, aortitis, aneurysm, and the various types of neurosyphilis. The pathology of these small foci is that of syphilis in general: chronic perivascular infiltration with lymphocytes and plasma cells, endarteritis, reduction of the blood supply with ensuing degeneration of the parenchyma and replacement with scar tissue.

In order to make a diagnosis of latent syphilis, it is essential that one should get a history of syphilis or a positive blood test, accompanied by a negative physical examination, or in the case of a female, the birth of a syphilitic child. One should be very critical of a history of syphilis as experience teaches us that many patients have been told, on insufficient evidence, that they have that disease. Of great help in determining the probability of infection is a letter from the physician who made the diagnosis, stating signs and symptoms present at the time, and whether they were confirmed by a darkfield examination, spinal fluid examination, or blood tests, if by the latter, how many specimens were found positive and by what laboratory. It is desirable, also, to obtain information regarding the age of the infection, the date treatment was started, the kind and amount of treatment given, and the character and severity of any reactions. These data bear directly on the possibility of cure having been achieved and aid us in determining whether further treatment or periodic examination is indicated.

On the other hand a negative history of syph-

ilis is of no value as many patients with late syphilis (estimated by Moore as thirty per cent of all males and sixty per cent of all females) give no history of infection. Some of these patients may have had lesions that, because of their insignificance or location, escaped detection, or were incorrectly diagnosed, as occurs so frequently with extragenital chancres, while others may have had a symptomless infection, which Moore thinks occurs with relative frequency and he hazards a guess that at least one man in every five and one woman in every three who acquire syphilis do so without ever developing any lesions recognizable as early syphilis.

It is customary to accept as clinically latent those cases which in the presence of a completely negative physical examination have a positive blood test. In fact it is often the only evidence of infection present. In such cases the blood test should always be repeated at least once, possibly in a different laboratory or by a different method. Serologists and syphilologists generally agree that a technically correct, repeatedly and unqualifiedly positive reaction with any of the standard tests means syphilis if we can exclude yaws, relapsing fever, trypanosomiasis, and possibly leprosy and malaria. After the primary stage, positive serology is the most trustworthy and sensitive indication of syphilitic activity. (A point to be remembered is that syphilis is not a respecter of class and the significance of positive serology should not be minimized, as is sometimes done, when found in a person considered "above suspicion.")

But repeatedly negative blood tests in untreated cases do not mean that syphilitic infection is not present as the spirochetes may be temporarily in check, or the foci may be so small that not enough reagin is being liberated into the blood stream to produce a positive reaction. Sometimes, as we have shown above, a blood specimen may be negative by one method and positive by a more sensitive one. Then, too, we have seen secondary syphilis and paresis, both of which we associate in our minds with positive tests, show repeatedly negative ones.

The physical examination should be performed thoroughly always and a search made for any clinical evidence of activity. Careful note should be made, also, of the presence of any concomitant disease. In the early cases the possibility of infectious recurrences should be kept constantly in mind, and a most thorough examination of the skin and mucous membranes made with special reference to mouth, genitals and anal regions, palms and soles. In the late cases attention must be given to the cardiovascular and nervous systems, liver, eyes and ears, as one or more of these parts are liable to be the site of crippling or killing lesions. Because

no one person can hope to master all these fields, the cooperation of specialists is desirable.

We have found the Hinton blood test very reliable in determining the absence of neurosyphilis. Although I have not tabulated our results, I venture to estimate that a negative Hinton test on the blood will be accompanied by a negative spinal fluid in ninety-eight per cent of cases. Since arriving at this conclusion I must confess that although a spinal fluid examination is always desirable, I have not so earnestly urged lumbar punctures if the Hinton test shows the blood persistently negative and there are no positive neurological signs or symptoms. If, however, the Hinton test is positive I am very firm in my belief that a spinal fluid examination should be made unless contraindicated by the presence of old age, pregnancy, advanced heart disease or arthritis. If the spinal fluid is found to be positive, the case is classified as neurosyphilis, and treated accordingly.

While the Wassermann is the only finding in the spinal fluid diagnostic of syphilis, the cell count, total protein, globulin, and gold sol tests should always be done as these assist in determining the intensity and type of involvement, and act as a check on the result of treatment. It must be understood that active vascular neurosyphilis and tabes are not infrequently accompanied by negative spinal fluid.

A large percentage of pregnant syphilitic women are in a clinically latent state and the presence of infection can be recognized only by positive serology or by the birth of a syphilitic child. It is because of this that in questionable cases, all the children should be examined. It is also well known that there is usually developed a degree of resistance much greater than that present in non-pregnant women and in men. Kolmer says of this that "it would appear that the enhanced immunity of the pregnant subject is due to a reinforcement and if such is true, one naturally suspects that the new tissues of pregnancy are actively concerned in the process, since it has been shown that they are frequently infected." At times, however, pregnancy may be accompanied by the most persistent lesions, suggesting a lowering of resistance.

If, after thorough study, we have arrived at a diagnosis of latent syphilis, the question naturally arises as to the proper course to pursue. Our decision rests on a critical evaluation of the factors presented in the individual case and not on the simple and too frequently used formula the patient's blood test is positive that means he has syphilis and the treatment of syphilis is arsphenamine. A discussion of these factors should give us all a better understanding of the indications for treatment.

The dangers of untreated latency and the fact that latency may be maintained throughout life have been discussed. It is interesting

to speculate on the probable outcome in a person with untreated latent syphilis. Moore says, "Assuming that the disease has existed for at least four years, so that the patient's own defense mechanism has had time to become firmly established, that searching physical examination has revealed no lesions especially of the cardiovascular and central nervous systems, and that the cerebrospinal fluid is negative, one is probably justified in predicting that a given patient if he receives no treatment at all at best has only about 2 chances in 10 of developing any serious trouble, at worst, not more than 3 chances in 10. If lesions do occur, there is probably not worse than an even chance that they will be incapacitating, and cardiovascular involvement is the chief serious risk which must be feared. The danger of the development of neurosyphilis (probably excepting only a more or less purely vascular involvement) is largely past by the time true latency is achieved."

The prognosis in untreated early latency, i.e., of less than four years' duration, is more indefinite as it is impossible to predict how adequately this defense mechanism will be developed. Until such time as we are able to determine accurately the outcome of the infection in each individual treatment in some form is usually indicated, and, as shown by Moore, it will reduce the probability of progression, relapse, and death from a probable twenty-five to thirty per cent to about five per cent, and the percentage of Wassermann positive but clinically latent cases from thirty-five to 75 per cent. The danger of death when the patient has had two years of modern treatment is estimated by Cole as 0.3 per cent.

And so, having decided that treatment is indicated, we must ask ourselves what we hope to accomplish and how to achieve the maximum good with the minimum harm. Most cases of primary or secondary syphilis occur during the years of sexual activity. The patients are usually in vigorous health and the spirochetes have not had time to barricade themselves behind fibrous walls or to cause any serious destruction in vital organs. Therefore an intensive routine attack is generally applicable and will result in a large percentage of what, to the best of our knowledge, may be regarded as cures. This therapeutic attack, an outline of which will be given, must be vigorous and continuous, our main reliance being placed on one of the arsphenamines, the most potent and dangerous drug used in the treatment of syphilis. The earlier treatment is started, the better the chance for cure, our dependence being on the drugs rather than on the patient's natural resistance. In this type of case, and early latency may be included, we are justified because of the possibility of eradicating the disease and because the age of the patient is favorable, in taking more chances than would be advisable in late cases.

Following the secondary stage, the probability of cure diminishes with the passage of time and after an indefinite period (placed by Moore at more than four years), biological cure is rarely achieved. This being so, we can in those cases where latency has been established temper our therapeutic attack to conform to the indications present. If we can prevent infection in others and maintain a state of latency throughout a long and uneventful life, even though at autopsy the pathologist finds a few spirochetal rests, we have accomplished all that is possible with our present knowledge.

As has been mentioned in early syphilis our therapeutic attack is led by one of the arsphenamines. In contrast, when treating late syphilis whether with obvious lesions or when the disease is considered latent, one should make a hard and fast rule to start with the less potent drugs such as mercury, the iodides, or bismuth. This is called preparatory treatment and should continue for one or two or three months, or even more as in cirrhosis of the liver, before arsphenamine is even considered. (If arsphenamine is finally given, not more than 0.1 Gm. should be administered in the first dose even though there appears to be no contraindication.) This rule, to be sure, is broken frequently and, in a vast majority of cases without any serious trouble ensuing, but serious accidents, including death, doubtless occur with more frequency than we can know as they are not generally proclaimed. They must be guarded against since they are in large part preventable, and adherence to the rule will do much.

These accidents are due to what is known as the Jarisch-Herxheimer reaction, or therapeutic shock which manifests itself by causing an exacerbation of syphilitic lesions associated with hyperemia and edema. The physician can do much to avoid such complications by refusing to allow himself to be hurried, and by working to promote a slow though steady resolution of the lesions and the establishment of the best possible collateral circulation.

While mercury and bismuth may cause mild reactions arsphenamine, probably because of its greater spirocheticidal properties, is the chief offender. This trouble is caused, it is thought, by the rapid destruction of large numbers of spirochetes and the liberation and absorption of their endotoxins. There must be however, another factor involved, since these accidents may occur with the treatment of late lesions which do not contain many spirochetes. This reaction, if it is to occur, will follow the first dose provided that the amount and the quality of the drug are correct. There will be noticed about two hours after the injection a constitutional reaction with a fever running from 100° to 103° or more and lasting from six to twenty-

four hours. Locally there will be an exacerbation of existing lesions and frequently the appearance of a roseola and urticaria-like lesions which may last a day or two.

The appearance of the reaction in primary or secondary syphilis is usually of no great import, whereas a similar reaction with edema involving lesions in some vital organ may result in serious symptoms or death. Coronary occlusion is probably the most common cause of death resulting from this complication, though aneurysmal rupture, cerebral hemorrhage, laryngeal occlusion, ascites, jaundice, or acute albuminuria may occur. The medical care should be along common sense lines.

In early latency the possibility of the infection being transmitted to others including the progeny should be borne in mind and precautions taken. As we depend in large part on the developed resistance in maintaining the state of latency, avoidance of injury, mental and physical strains will be helpful as will the usual hygienic measures such as fresh air, good food, and an adequate amount of sleep. Liquor in moderation to those accustomed to it may be allowed and smoking is permissible, except in the presence of recurrent infectious mouth lesions or leukoplakia. Focal infections, not overlooking the prostate, should be eradicated if possible as their products apparently are factors in the production of treatment reactions. Special attention should be given to the bowels and kidneys since they are the organs chiefly concerned in the elimination of the drugs used at this time. The condition of the kidneys was included in the physical examination. If albumin or other abnormal findings are present, this fact should be given due consideration in the treatment scheme, remembering that renal irritation is more likely to be caused by mercury than by bismuth or neoarsphenamine. In such circumstances the urine should be examined before each succeeding injection and future treatment determined by the findings. The prevention of stomatitis is also of great importance and may be accomplished by oral hygiene and dental care.

As with many things in life, the treatment of syphilis is a compromise. The physician, because it requires less time and skill, may substitute neoarsphenamine for the more efficacious arsphenamine, the patient because of expense, discomfort of injections, or inertia, may not be willing to come two or three times a week for an injection of soluble mercury or bismuth, though in his particular case one of these preparations may be especially indicated, again the patient may take an occasional mercury pill but may balk at injections. In spite of these difficulties, efficient treatment for latent syphilis can be planned which will require, except pos-

sibly during the first two weeks in early latency, only one visit a week and which will reduce the pain and discomfort and will minimize the cost. This will be of great assistance in maintaining regularity throughout the duration of the treatment period.

Detailed discussion of the drugs used in the treatment of syphilis is beyond the scope of this paper though for our purpose brief mention is necessary. Arsphenamine ("606") is generally admitted to be the most efficacious spirocheticidal agent we possess and is to be preferred in the treatment of early syphilis especially. Because of technical difficulties in its preparation and administration, as well as the greater frequency of reactions following its use, neoarsphenamine is used as a substitute by practically all general practitioners and many syphilologists. Therefore in outlining treatment in this paper, neoarsphenamine will be the arsenical used unless otherwise stated.

Believing as I do that large doses i.e. 0.9 Gm., besides being more toxic, exert a depressing effect on the patient's natural resistance and defeat in part the purpose for which the drug was given I suggest a maximum dose of 0.6 Gm. which I believe will accomplish all the good possible with less danger of harm. An arsenical course will consist of ten injections. The dosage in patients under 120 lbs. including children is figured on a basis of 0.1 Gm. to twenty lbs. body weight. I do not advise smaller doses in females as I have found that females weighing 120 lbs. or thereabouts generally have fewer reactions than do heavyweight prize-fighters or policemen weighing 200 lbs.

The initial dose in early latency should not be more than one-half the maximum dose for the individual. In late latency, to guard against serious reactions occurring in clinically unrecognized lesions, I repeat that the initial dose should always be small i.e. 0.1 Gm. 0.15 Gm. Each succeeding dose in the absence of contraindications may be increased approximately 0.15 Gm. until the maximum for the individual is reached. Though the maximum dose of 0.6 Gm. is used by many syphilologists in the treatment of pregnant women without ill effect, it has been our custom, because of the additional burden pregnancy places on the patient, to be content with a dose of not more than 0.45 Gm. unless the infection is in the primary or secondary stage in which case a dose of 0.6 Gm. is advisable.

Bismuth ranks next to the arsenicals as a spirocheticidal agent and has largely replaced mercury in the treatment of syphilis. There are many so-called soluble and insoluble preparations on the market. An insoluble oil suspension is suited for our purpose and of the many I personally use either bismuth salicylate or iodobismuthate of guanine in doses of 0.2 Gm. at weekly intervals for fifteen injections.

(Larger doses produce no better clinical results and carry more danger of stomatitis.) Of the two preparations the latter is less painful, in fact I think it is the least painful of all bismuth preparations and is less likely to cause a bismuth line or stomatitis than the salicylate, probably because of a lower metallic bismuth content. The manufacturers claim the iodobismuth molecule exerts a synergetic action but I judge its therapeutic action about the equal of the salicylate. A desirable feature of the insoluble forms of bismuth, as with mercury, is that they are slower of absorption and their action is of longer duration than that of the soluble forms.

Mercury, except for its use in preparatory treatment and in old people with an infection of long duration, does not play any part in my treatment plans. It may be taken by mouth alone or with iodides and accomplish its purpose without the pain of injection and the time consuming messy injections though gastrointestinal upsets are more prone to occur. Any of the following tablets may be used three times a day, after meals. The dosage is for adults.

- R Hydrargyri chloridi corrosivi gr 1/16
Extracti glycyrrhizae qs
R Hydrargyri cum creta gr 11 to 111
R Hydrargyri protiodidi gr 1/4 to 1/2

Of the iodides, potassium though not so well borne as sodium, has greater therapeutic value and is our choice. An ascending dose of gr v xxx well diluted with water or milk three times a day on an empty stomach, is usually well borne and sufficient for our needs. It may be used alone or in conjunction with any of the drugs mentioned. A common method is to take it for two months and then omit for two months. In the days when mercury and iodides were our only weapons in the attack on syphilis, the iodides were indispensable in treating the late manifestations. This is no longer true and today we need not be disturbed as a rule, if because of reactions we are forced to discontinue the use of iodides as both the arsenicals and bismuth will cause granulomatous infiltrations to be absorbed with even greater rapidity if this should be desirable as in gumma of the palate with impending perforation.

In contrast to syphilis with clinically recognizable lesions where a definite line of attack is clearly indicated late syphilis offers the clinician an opportunity to exercise his judgment to the fullest extent, and a marked difference of opinion regarding treatment may be found among those with equally extensive clinical experience. As a basis for comparison I submit the following treatment scheme which has proved satisfactory and applicable to the average adult with early syphilis. Every syphilologist has his own favorite scheme but the opinion is practically unanimous that continuous

transmitting the disease has passed and I have never seen an unquestionable case of third generation syphilis

Positive serology plays a large part in the detection of latent syphilis and its frequent persistence, (in the so-called Wassermann-fast or serologic-fast cases) despite intensive treatment, causes the patient and the physician much concern. As has been mentioned, this positivity varies with the sensitivity of the test employed. My experience with routine Hinton, Kahn and Wassermann tests on private patients, examined in Hinton's laboratory during the past five years, has shown the Hinton test to be the most sensitive and without loss of specificity, the Kahn rates next, but it is so unusual for either the Kahn or Wassermann to be of any help that this procedure has been discontinued as a routine measure and reliance placed on the Hinton alone. Serologic fastness can be prevented in practically all cases if the treatment outlined for early syphilis is given during the primary or secondary stages. Faced with its presence, we must search thoroughly for lesions especially of the cardiovascular and nervous systems: viscera and bones, as involvement of one or more of these structures is frequently found to be the cause of this persistent positivity. If none is found, one must assume their presence though they are too small for clinical recognition.

I believe with Kolmer that fixed positivity means the presence of active foci and I advise treatment as outlined for late latency followed by reexamination at least once a year. I feel that it is a mistake to lay much stress on the result of blood tests as the patient is likely to exaggerate their importance and if one becomes negative, to stop treatment in early syphilis, or to worry unnecessarily if it remains positive. Moore states that the studies of the Cooperative Clinical Group have shown that in latency, Wassermann-fastness is not of grave significance, that relapse and progression are no more frequent among Wassermann-fast patients

than in those with more easily reversible tests and that the tendency toward spontaneous reversal of the Wassermann after treatment is the rule.

Operations on a patient with a positive blood test, except in an emergency, should be delayed until after one or two months' treatment has been given. Treatment should, of course, be resumed after the operation. Surgeons often refer patients for treatment with the remark that they will operate when the blood becomes negative. This is entirely unnecessary and in many with late latency would mean that the patient would forever be deprived of the benefit of surgery as it may be impossible to reverse his blood to negative. The danger lies in operating on gummatous lesions as it is unusual for uninvolved tissue to show any indisposition to heal.

It must be remembered that there is no positive test during life to determine the presence of cure or pathologic latency and that all patients who have had syphilis should be examined at least once a year throughout the remainder of their lives. I wish, also, to call attention to the fact that we do not know the exact amount of treatment necessary to accomplish our purpose in each or any individual. One-half of the treatment outlined may cure a given case and twice as much may not prevent progression in another. To some the treatment herein outlined may seem excessive, but experience has shown that it will accomplish more good than markedly lessened amounts without increasing the incidence of serious complications which after all usually occur at the beginning or early in the course of treatment.

MYXEDEMA HEART WITH CONGESTIVE HEART FAILURE AND POLYSEROUS EFFUSIONS*

BY LEWIS M. HURXTHAL, M.D.†

SUFFICIENT evidence has accumulated in the literature to show conclusively that the heart in high grade myxedema undergoes physiological changes which may be demonstrated by circulatory, roentgenologic, and electrocardiographic studies. In 1929 observations were begun in this Clinic on the heart in cases of myxedema before and after treatment. Our findings were in accordance with previous and subsequent papers which demonstrated a shrinkage in the size of the heart shadow after administration of desiccated thyroid^{1 2 3 4 5 6 7 9 12 13 14 15 16}. Since so few of the recorded cases in

the literature have shown such striking evidence of congestive heart failure as was present in one of our cases, it is being herein reported.

That the enlarged heart shadow found in cases of myxedema is not entirely due to dilatation, in some instances at least, has been demonstrated by Gordon⁷ and Freeman¹⁵, both of whom withdrew large amounts of fluid from the pericardium. Pericardial effusion was suspected in our case. A pericardial tap was attempted but no conclusion as regards the presence of pericardial effusion could justifiably be made although there was no doubt that the pericardium had been punctured. In both cases reported by Gordon and Freeman there was also evidence of dependent edema and in one the

liver was enlarged Zondek¹ and Fahr² have reported instances of congestive heart failure in myxedema

CASE REPORT

The patient was an American born woman sixty three years of age. She had been married forty years and had two children one of whom was living and well. Her husband was living but in poor health. She entered the Clinic on October 2, 1929.

The chief complaint was shortness of breath and swelling of the abdomen. In January of the same year she had had an acute illness called "flu." Four months later she began to notice dyspnea. In August the dyspnea had increased and while having a dress fitted she noted that her abdomen was enlarged. From August until October dyspnea further increased and orthopnea appeared. She further stated that she had always felt colder than other people and as a consequence had worn more clothes. Perspiration had been practically absent for a long time and her speech had always been slow. During the year before admission she felt that she had slowed down both mentally and physically. She was referred to the Clinic by Dr. E. R. DeRoma of Walpole, Massachusetts who made the diagnosis of myxedema. Upon advice of her physician she had taken desiccated thyroid but not according to directions omitting it frequently. She felt that it upset her stomach made her constipated and increased the stiffness of her joints.

Her past history revealed that she had had scarlet fever and typhoid fever. In 1889 one tube and ovary had been removed. The menopause occurred at forty nine years of age and there had been no flow since that time. Her average weight was approximately 145 pounds. One year before admission it was 151 and in September 1929 two months before admission it was 163. In 1926 she had had "eczema" and for years had had "rheumatism."

On physical examination there was no question as to the presence of myxedema. The bloated faces, the dry skin, the retarded mental state were all present. The neck veins were prominent, the thyroid could not be palpated. The heart appeared enlarged to percussion, the rhythm regular, the

sonnds distant and of poor quality. The blood pressure was 155 systolic 110 diastolic there was a paradoxical pulse, the rate was 60. There was a hydrothorax on both sides apparently more marked on the left. The margin of the liver was down low as revealed by palpation and there was tenderness in this area. The abdomen was distended and it was thought that a definite fluid wave could be elicited. There was pitting edema of the lower legs, thighs and sacral region. The patient breathed comfortably only when propped up in a semi-reclining or sitting position.

The patient was sent to the hospital and the accompanying observations were made the following day.

The basal metabolic rate was -36 the pulse 60 to 72 the blood pressure 172/100 and the weight 152½ pounds. The red blood count was 3,760,000, white blood count 6,600 and hemoglobin 65 per cent by the Sahli method. The differential count showed 60 per cent polymorphonuclears, 29 per cent lymphocytes, 6 per cent monocytes, 3 per cent eosinophiles and 2 per cent basophiles. The blood smear appeared normal. The blood nonprotein nitrogen was 33 milligrams per 100 cc. The Wassermann reaction was negative. Phthalein excretion was 35 per cent in two hours with a urine volume of 290 cc. The urine contained no albumin or sugar, showed a specific gravity of 1.008 and a neutral reaction. The sediment was negative. Other twelve-hour specimens of urine varied in specific gravity from 1.007 to 1.018.

The seven foot roentgen ray exposure of the heart and the electrocardiogram taken on October 20, 1929, as well as subsequent observations are shown in plates I and II. The clinical course as shown by the clinical chart is reproduced in fig. 1.

PLATE I

A. Seven foot roentgenogram, taken October 6, 1929, before treatment.

B. Seven foot roentgenogram taken November 6, 1929; roentgenograms taken a month after treatment as well as a recently (1924) are essentially the same as shown above.

On the third day of the hospital stay paracentesis of the pericardium was attempted. A moderate-sized needle was inserted through the chest wall at a point lateral to the usual position of the apex. Fluid was immediately encountered but after a few cubic centimeters were withdrawn the flow ceased. The needle was then pushed in a little farther when it was apparent that it was touching the heart muscle. No fluid could be obtained and the needle was withdrawn as it did not seem desirable to poke about especially if the heart was dilated. No conclusions could be made from this attempt because I am not certain that the fluid came from the pleural

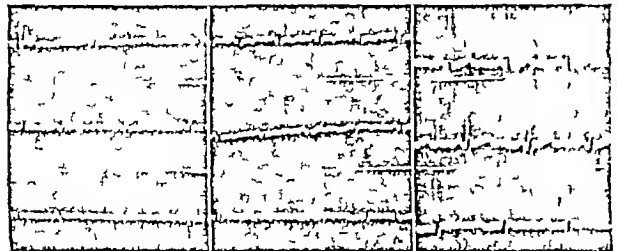

PLATE II. Leads I, II, and III (top to bottom) of electrocardiograms taken before 10 days and 30 days after treatment.

or from the pericardial cavity. The amount withdrawn was not sufficient to determine the specific gravity.

Thyroxin (1/80 grain) was given daily after the first metabolism was determined. No other medication was administered. During the first four or five days in the hospital, the patient slept a greater part of the time. This lethargy gradually passed away so that by the end of two weeks she was mentally alert. All evidence of edema had disappeared and there remained only a small amount in the left pleural cavity.

The patient was incapacitated for a few weeks after leaving the hospital but by the end of two months was able to resume her normal activities. About eight months later she developed pain in the back and rather severe attacks of sciatica. Following tonsillectomy on August 26, 1930, physiotherapy, and the wearing of a fitted corset, these complaints ceased. The patient now considers herself in fairly good condition for her age, which is sixty-eight. She does most of her housework. She sleeps well, eats normally, and is not bothered with dyspnea or palpitation. The optimal dose of thyroxin has been established at 1/80 grain five times a week.

The blood pressure has not changed remarkably throughout, although there has seemed to be a lower average diastolic pressure since taking thyroxin. In a roentgen plate taken at the time she had sciatica,

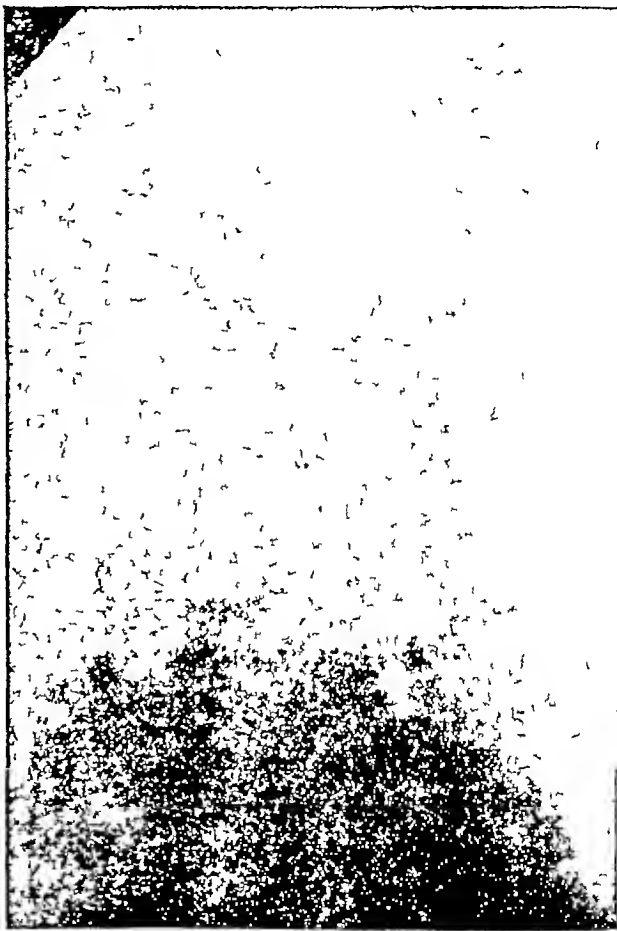

PLATE III. Roentgenogram of abdominal aorta showing extensive calcification.

evidence of marked arteriosclerosis was found as shown by calcification of the abdominal aorta and iliac vessels (Plate III).

Observations of the Basal Metabolic Rate, Pulse, Blood Pressure, and Weight after leaving hospital:

Dose of 1/80 grain Thyroxin Tablets per week	3½	4	4	4	5	5

DISCUSSION

There can be little doubt that this case was one of severe myxedema with the usual clinical features of congestive heart failure. Whether the fluid as found in the pleural, pericardial, and abdominal cavities in such cases is the direct result of congestive heart failure or is partly an exudative accumulation from myxedema per se is not as yet proved. In the case described by Freeman, diagnosed as chronic pericarditis and effusion, withdrawal of the fluid alone was followed by marked improvement for three months. This observation, I believe is the most important one yet recorded in relation to this question. Had the heart failure and consequently the patient's disability been entirely due to myxedema alone, it would seem unlikely that he would have received so much benefit from the pericardial tap without administration of thyroid. I believe, therefore, that one is justified in concluding that the end result as illustrated by the case reported here comes about as follows: first, the absent or diminished secretion of thyroid causes the heart to dilate and become sluggish; secondly, in severe cases serous fluid accumulates, probably as an exudate, in the various cavities; and thirdly, the combined effect of a sluggish heart and the mechanical embarrassment of the heart by the serous fluid produces the clinical picture of congestive heart failure.

From a therapeutic point of view, it makes little difference which theory is correct as the administration of desiccated thyroid or thyroxine alone suffices to relieve the patient entirely. This subject has, however, an important bearing on the recent therapeutic procedure of total thyroidectomy¹⁷ for congestive heart failure. If such an extreme state of circulatory failure can result from marked myxedema, it would seem that the production of myxedema might well defeat the purpose for which it is intended. The reported cases of myxedema which show congestive heart failure have apparently been of severe type. Thus, it would appear that

following total thyroidectomy, only a mild or moderate degree of thyroid deficiency should be allowed to develop and that a small amount of desiccated thyroid should be given to prevent severe myxedema.

CONCLUSION

A case of severe myxedema is presented in which there were the usual signs of congestive heart failure and polyserous effusions. The patient has been under treatment for six years and continues to be well. It is suggested that the appearance of congestive heart failure is the result of myxedema heart and the mechanical embarrassment of the circulation occasioned by the accumulation of effusions which are the result of myxedema and not of heart failure. The possible relationship of this syndrome to total thyroidectomy is discussed.

CANCER EDUCATION IN MEDICAL SCHOOLS*

BY ROBERT B. GREENOUGH, M.D.†

I WANT to thank you for your courtesy and your indulgence in inviting me to deliver the Eleventh Lewis Linn McArthur Lecture of the Frank Billings Foundation of the Institute of Medicine of Chicago, an honor of which I am deeply sensi-

*The Eleventh Lewis Linn McArthur Lecture of the Frank Billings Foundation of the Institute of Medicine of Chicago held on February 1, 1935.

Reprinted from the Proceedings of the Institute of Medicine of Chicago Vol. 10 No. 12 March 15 1935 by permission of the Committee on Publications.

†Greenough, Robert B.—Consulting Surgeon, Massachusetts General Hospital and Collis P. Huntington Memorial Hospital. For record and address of author see "This Week's Issue" page 10.

ble and which I fear I shall find it hard to justify.

Let me first, however, record the fact that the death of Lewis Linn McArthur, which occurred since the lecture was last given in 1934, is a loss which the surgical profession of the whole country, and indeed of other countries, shares with you who lived with him and experienced daily that unparalleled combination which he possessed of keen judgment and exquisite surgical skill tempered by modesty even to the point of diffidence and humanized by

the milk of human kindness. Such were the striking features of his professional career. May this unique influence long endure as an example to us who follow him, and let us believe that it was with this intent that Doctor Billings established the McArthur lectureship as a part of the foundation.

Many different influences have contributed to the determination of the changes which have taken place in the undergraduate medical curriculum since the turn of the century. Among these may be mentioned, perhaps first, the great advances of medical science which have made it necessary to discard much of the empiric instruction of the 80's and 90's, and to replace this by the more rational scientific methods which have contributed in such great degree toward these same advances. Other considerations, however, have influenced the instruction in our medical schools, such as the varying educational requirements for licensure in the different states of the union and the elimination of the low-grade and proprietary medical schools and the development of the strong university schools along the lines of the sound educational principles already established in the other graduate schools of the universities. Since these influences have been felt to be of somewhat unequal significance in different localities, it is not surprising that wide differences should still exist between the different schools in the general educational policies adopted and in the details of the curriculum offered to the prospective student.

During this same period also, the requirements in the way of premedical instruction have been extended to at least two years of college education in all of the approved schools and, what is of very great significance, the number of candidates for admission to these schools is so greatly in excess of the number of students which can possibly be admitted that a process of natural selection has taken place, with the result that the intellectual and scientific qualifications of the medical student of today are vastly greater than they were twenty-five years ago.

These considerations have also affected the technical form of instruction given, as well as the content of the curriculum. Thus the didactic lecture has been almost completely abandoned. Its place has been taken by laboratory work, conferences, and clinical instruction, and the tendency here has been progressively to deal with smaller and smaller groups of students, and to have the student actually take part in the exercise and not remain an observer on the side lines. This clinical instruction is supplemented by collateral reading from textbooks and from contemporaneous medical literature and by conferences of smaller groups. More time is spent both in the laboratories and in the clinics in

teaching principles and methods than in acquiring a mass of uncorrelated facts. The concept of preparation of the student for a life-time continuance of the study of medicine, through school, hospital, and practice, is set up, and the discipline of self-instruction is the objective rather than the acquirement of isolated facts which too frequently will be forgotten before the need for their use occurs.

With this change in the medical curriculum has come about a more widely accepted recognition of the fact that the four-year course in medicine, and the M.D. degree which indicates its successful conclusion, can no longer be considered sufficient without an additional year or years of hospital training, to ensure the qualifications of the graduate to engage in the general practice of medicine with safety to the public. Under these circumstances it becomes necessary to consider first what absolute essentials of knowledge must be acquired in each department of the medical school to serve as a firm and substantial foundation on which to base subsequent hospital experience, in order that the student may consolidate the whole into such a structure of coordinated knowledge and experience as to qualify him for the actual practice of his profession.

It is of course to be expected that each department of the school should regard its own subject as of greater importance in this composite foundation than that of other departments, and only a wise and impartial authority and one endowed with force and tact, can bring these divergent units into a freely cooperative group. When this is accomplished, however, and the medical course is viewed as a composite period of learning in which all departments must contribute to the desired end, the first and foremost difficulty is overcome.

Since it is instruction in the subject of cancer that concerns us here, let us consider first the basic knowledge of that subject which we may agree is needed by the student when he completes four years of medical school and clinical instruction and qualifies for his hospital intern service and his degree. Let us consider also the further knowledge which he should acquire in his intern training in order that on graduation he may give efficient service to the community as a general practitioner, and finally, that minimum of knowledge of cancer which will make it safe for him as a surgeon or a radiologist to undertake the actual treatment of cancer in the individual patient. We can then judge the extent to which cancer instruction, as commonly given today in our medical schools, conforms with those ideals. In doing this, however, we must always bear in mind that cancer, though undoubtedly of great importance in mortality statistics, is only one, and by no

means a common one, of the multitude of diseases with which the practicing physician must be familiar and further, that however desirable it may be that the practicing physician's working knowledge of cancer should be increased this end will have to be attained under present day conditions by increasing the efficiency of the instruction given to him as an undergraduate rather than by any material addition to the hours in this curriculum allotted to this subject.

The unique and practical feature of cancer as a disease is, of course the fact that while readily cured in many situations by removal or destruction in its early local stages in its later disseminated stage it has a 100 per cent mortality. This is not true of any other disease which afflicts so large a percentage of the population as cancer. It is for this reason that the early diagnosis of cancer assumes a significance far greater than that of many other conditions the majority of which are definitely designated as self limited diseases because of the fact that the natural protective processes of the human body, once set in motion, not infrequently can operate successfully to overcome the disease. This does not occur with cancer. It is a fact furthermore that the early diagnosis of cancer is established only with the greatest difficulty whereas the later symptoms are too often unmistakable. Much has already been accomplished in the way of education of the public to secure prompt consultation by the patient with a physician on the recognition of any suspicious symptoms, but a great deal more remains to be done along this line. Unless, however the physician is alert to recognize the possibility of the presence of cancer as a cause of the symptoms of the patient who consults him and unless he immediately takes steps to obtain a positive diagnosis, whether by roentgen ray or instrumental examination or biopsy or by consultation the chances of that patient being permanently cured of cancer diminish steadily day by day. Studies made by Dr G. A. Leland at the Huntington Hospital indicate that cases of cancer of the cervix of the uterus require on an average only four weeks' time to progress from the early favorable to the more advanced class, with a corresponding diminution of the percentage of five year cures of 16 per cent or 4 per cent a week. Under these circumstances we may fairly insist that no student should reach the end of his fourth year in the medical school without having the overwhelming importance of the early diagnosis of cancer so firmly fixed in his mind as to make him ever after feel a sense of personal responsibility for any cancer patient who progresses from the local to the extended stage of the disease by reason of his failure to secure a prompt diagnosis in a suspected case which has consulted him.

Undergraduate instruction in cancer begins in almost every medical school as a part of the

course in pathology and usually in the second year. Instruction is given by lectures and in the laboratory. The student learns the general features of the cancer process such as the histological and gross appearances of cancer in its established stages, and the different methods by which cancer of different cellular composition and arising in different situations extends to other organs. Attention is given to precancerous conditions and to the study of material from the operating rooms, as well as from the autopsy table, in order that the student may become familiar with the disease in its early as well as in its more advanced and fatal stages. Emphasis is not infrequently laid upon the protean character of the disease, but the symptoms of cancer of different organs and the differential diagnosis in each situation must be left as a rule to the later clinical instruction of the third and fourth years. Contemporaneous clinical demonstrations are arranged in some schools as correlative exercises to the course in pathology, in order that the student may gain some idea of the appearances in the living patient of the disease which he is studying in the laboratory. Cancer and other tumors are, of course, included in these exercises.

The important knowledge of cancer which has been acquired by research workers studying transplantable, spontaneous and induced cancer in animals and the significance of heredity, together with the practical application of these facts to the etiology of cancer and to the prevention the diagnosis, and the treatment of cancer in human beings, are properly included in this portion of the course.

At this point also the public health aspects of cancer are commonly presented. The world wide and continued increase in the cancer death rate and its significance is discussed together with the necessity for the education of the public as well as of the medical profession to the importance of early diagnosis and the efforts which have been made to provide convenient consultation facilities by the establishment of cancer hospitals and cancer clinics in all civilized countries.

This basic instruction in pathology is further elaborated in many schools by a course in surgical pathology, given in the second or third year in which the clinical and the laboratory aspects of cancer as well as of other surgical diseases are brought together and correlated to such a degree as is possible with the clinical material available in the hospital and the resources of the laboratory which receives the operative material of the hospital for study and diagnosis. In such a course a practical but very elementary comprehension of the refinements of the histological diagnosis and the classification of tumors can be given. Such matters as the grading of malignancy can be discussed, and the subject of radiosensitivity, which is becoming more and more an important considera-

tion in radiotherapy, can be brought to the student's attention. Such a course in the surgical pathology of tumors must be acknowledged to be one of the most important features of the teaching of cancer in medical schools which have been developed in recent years, and may, as in some schools, be postponed to the third or fourth year.

During the third and fourth years of the medical school, when the student begins his clinical work in the wards and outpatient departments of the hospital, he first comes in contact with cancer as a disease in the living patient in its many different situations. Unfortunately, however, in the majority of our medical schools today this experience is obtained under the supervision and instruction of a large number of different teachers and in many different clinical departments of the school and hospital. Thus, while the main responsibility for clinical instruction in cancer rests undoubtedly upon the surgical department, medicine, gynecology, ophthalmology and otology, dermatology, genitourinary surgery, neurosurgery, and radiotherapy all present the subject of cancer to the student from one or another point of view.

Too often it is this part of the student's training that can be fairly criticized as lacking such correlation as to give to the student a clear and systematic comprehension of the cancer process as a whole, and of the general principles underlying its diagnosis and treatment in the many different situations in which it may develop in the human body. While this lack of coordination in the teaching of cancer exists in many medical schools today, it is found to be present also in regard to the clinical diagnosis and treatment of cancer in many of our hospitals. It is to correct this lack of coordination between the different clinical departments of our hospitals, and to tie them up more closely with the basic knowledge of cancer which is to be derived from the department of pathology and with the rapidly advancing knowledge of radiotherapy, that the movement for the establishment of cancer clinics in general hospitals has come about. In the past seven or eight years the development of clinics of this nature, staffed by representatives of all these different departments of the hospital but operating as a cooperative group for the discussion in conference of the diagnosis and treatment of the individual case, has been conspicuous. Many of the great university medical schools have been quick to see the advantages of this opportunity for the student to obtain a broader view of the subject of cancer by utilization of the experience and material available in the cancer clinic. Where such clinics do not exist, however, the student is obliged to attempt to correlate this knowledge for himself at a very considerable waste of time and with difficulties which are often almost insurmountable.

It may be maintained, as indeed has already been stated (in the report of the commission on medical education 1932), that the task of correlating information derived from different sources and representing different points of view is a desirable mental discipline and, as such, a necessary portion of the student's training, but that this can easily be carried so far as to be a waste of the student's time is evidenced by the notable development of "combined clinics" and group clinics in many different departments of medicine, including the "pathological conference" which has been so widely adopted and is so highly valued as an educational exercise by the student, the intern, the staff, and the postgraduate as well.

Cancer in its many different situations in the human body is often spoken of as being not one disease but a whole group of diseases. From the point of view of the clinician this is undoubtedly true, because its clinical manifestations are so varied in these different situations that there are few if any symptoms of the disease which are common and characteristic of cancer in all its different places of origin. Especially is this true of cancer in its early stages when its recognition is so difficult and at the same time of such vital importance to the success of the methods of treatment upon which we now are forced to rely—surgery and radiation.

Thus cancer is a new growth or tumor, but the clinical demonstration of a tumor may be impossible from the clinical examination, as in cases of cancer of the stomach or of the colon, and resort is necessary to examination by roentgen ray. Some forms of cancer present themselves as ulcerative lesions, as in the mucous membranes of the mouth, and others are detected not by any signs whatever indicating their site of origin but only by the secondary manifestations of their extension to lymph nodes or by metastasis to bone, as in occasional cases of cancer of the breast or hypernephroma. It is these characteristics of cancer which make the differential diagnosis of the disease in each of its different situations a matter of separate and special consideration. Knowledge of these peculiar features of cancer in its different locations and experience in applying this knowledge to the diagnosis in the individual patient are thus important matters of experience to be brought to the student's attention during the third and fourth year clinical instruction in the wards and outpatient departments of the hospital.

At present, as a rule, this instruction is given independently by each of eight or ten different departments in the medical school and by their affiliated departments in the hospitals. Not only must this instruction cover matters of differential diagnosis, but the natural course of the disease in each of its different situations must be learned as well as the appropriate treatment in

each case, whether by surgery, by radiation, or by a combination of these methods. Discussion of safe methods for exploratory operation and biopsy in different situations is essential, and a consideration of the clinical features of the pre-cancerous diseases and conditions is of great importance. In the relatively brief period of clinic or ward service allotted to each student, and with the limited clinical material available it is not unreasonable to suppose that many of the less common forms may not be brought to his attention. Deficiencies of this sort in the schedule of clinical instruction are inevitable, but they may well be expected to be minimized if a cancer clinic exists in the hospital where the student is receiving his instruction and he is able to be present at the daily or weekly tumor conferences, in which the different departments concerned are represented and join in the study and discussion of the collected tumor material of the hospital.

In the matter of treatment also advantages are to be obtained by the student when he can have the relative merits of surgical and radiation therapy discussed by representatives of each of these departments, in a friendly and coöperative effort to determine for the patient that method of treatment which best meets the requirements of his individual case. This is an advantage to the student which he can rarely obtain from the individual instructor in one or another department who with the most sincere belief that he is imparting the truth as derived from his own experience, frequently exhibits a lack of precise knowledge of the results of treatment by methods other than his own, and a certain degree of prejudice which leaves the student in a state of confusion and unable to obtain authoritative information in regard to these controversial matters.

Where no cancer clinic exists in which the clinical material of the hospital can be collected, studied, and discussed by the student, the next best method appears to be that of the combined clinic which brings the instructors of two or more departments together to participate in a joint discussion of cases of cancer in its different situations. Such a combined clinic can be made to demonstrate the same group study principle which is the characteristic of the cancer clinic but requires special organization and does not so readily cover the entire field.

The instruction given in our medical schools today in roentgenology and radiotherapy varies within wide limits. The universal necessity for the employment of roentgen rays in the diagnosis of many diseases and the great importance of roentgen ray and radium therapy in cancer as well as in other conditions, have been recognized only within a relatively brief time and the science of radiology is one which is advancing rapidly at the present time. The necessity for a general knowledge on the part of the phy-

sician of its values and of its limitations is becoming more and more universally appreciated. It is not to be supposed that every graduate should acquire a comprehensive knowledge of the physics of radiology, or of the technique of roentgen ray examinations, or of the employment of radium and of roentgen ray in treatment, but the subject is of far too great importance to be left to the chance introduction of these subjects in connection with the instruction of the clinical departments in the third and fourth years. Many schools acknowledge these facts by assigning hours in the curriculum for such instruction, but in many instances this assignment is too short for any comprehensive course and in some schools scarcely any hours at all are given to this department.

What has been said about the undergraduate hospital instruction in cancer applies also to that of the hospital intern service with which the four years of medical school instruction is now commonly, if not universally, supplemented before registration to practice is sought in the several states. Here, of course, is given a much wider opportunity than during the undergraduate years, both in time and in clinical experience, to supplement the instruction already received, but here again unless the intern service is taken in a hospital which has its cancer work coördinated and collected in a cancer clinic, the varying experiences and prejudices of the different department staffs cannot fail to leave confusion and doubt in the mind of the intern, and delay or prevent him from acquiring that correlation of knowledge of cancer as an important disease which is to be desired.

At the end of four years of undergraduate instruction the student should have acquired a general knowledge of the pathological nature of the cancer process. He should know something of its etiology as a problem in biology. He should have firmly fixed in his mind the significance of long continued "chronic irritation" as an exciting cause of cancer, and through this approach he should acquire a grasp of the nature of "precancerous lesions" and the importance of their diagnosis and treatment in connection with the prevention of cancer in those situations where such conditions are universally accepted as of serious significance.

In addition to these general biological facts about cancer the student should know of its public health aspects of the steadily mounting cancer mortality, and of the statistical studies of the disease, not only in regard to its morbidity and its mortality, but in relation to the results of treatment in its different situations. He should know of the campaigns for education of the public and of the efforts made to arouse greater interest and proficiency among the members of the medical profession in dealing with cancer, and for increasing the resources for ex-

pert consultation and treatment by the organization of cancer hospitals and cancer clinics throughout the world. He should know also what can be done to diminish suffering and give the greatest ease and contentment to the incurable case.

He should be informed of the trends of present day cancer research, of the artificial production of cancer in man and in animals of the biochemical and biophysical studies of normal and of malignant cells, and especially of the studies of the influence of different chemical and biological products, hormones, vitamins and enzymes upon cell growth—a field at this moment under most vigorous cultivation in the research laboratories.

With this comprehension of the nature of the cancer process and its importance in present day medicine, the student at the end of four years of medical school with the clinical instruction in the hospitals of his third and fourth years should be aware of the vital necessity for prompt and accurate diagnosis of cancer in its more common situations, of the possibilities and probabilities of successful treatment by surgery and by radiation of the methods of exploratory operation which are regarded as safe and of those which are to be avoided as involving danger to the patient, and of those conditions which are widely recognized as precancerous diseases and which require prompt diagnosis and treatment that the occurrence of cancer may be prevented.

In addition to this knowledge of cancer in general specific instruction in regard to the differential diagnosis of cancer in its more common situations, especially those of the early case, must be acquired if the student is to fulfill his function as a general practitioner in the protection of the health of that part of the community which he serves. This knowledge must to a great extent be acquired by experience, and constant repetition may be needed to ensure its retention in such form as to be instantly available in the interests of the patient. Thus the differential diagnosis of cancer of the skin, breast, mouth, uterus, stomach and intestine may perhaps be set up as the forms of cancer which are most important from the point of view of frequency, followed by those of the bones, muscles and deeper tissues (the sarcomas), cancer of the genito-urinary tract of the esophagus, and of the glandular organs, such as the salivary glands, thyroid, and the pancreas.

With knowledge sufficient to cover the differential diagnosis of cancer of the more common regions or at least to realize the possibility of the existence of cancer in lesions of these organs the general practitioner can best serve his community by obtaining consultation promptly in cases where he is unable himself to make a

positive diagnosis. In performing this function he will fulfill his duty to society better by far than by attempting to supply the necessary treatment for such cases, unless he is equipped with adequate resources and experience.

The four years of the medical school can hardly be expected to carry the student much farther in his knowledge of cancer than has been above described. In his hospital intern service, however, the student is frequently obliged to choose between the medical and surgical services of the hospital. In many hospitals also additional intern or resident appointments are available in special departments, such as gynecology, genito-urinary surgery, pediatrics, orthopedics, otolaryngology, and ophthalmology. The surgical intern early in his career comes in contact with those forms of cancer which require and receive surgical treatment with or without the addition of radiation therapy. He thus learns the technic of exploratory operations in cancer cases as well as the complete standard radical operations required for the surgical cure of cancer. He assists at operations in cancer cases and may even obtain opportunity to perform such operations himself under supervision. Here again, however, the intern may be at the disadvantage of serving under a preceptor who may or may not be sufficiently interested in the modern group study of cancer to work in close cooperation with the pathologist and the radiotherapist. Where a cancer clinic has been organized this objective is readily attained. Where such is not the case, however, the fancy of the individual surgeon determines the extent to which the clinic study of cancer cases is pursued. During the surgical intern service, and in the special services such as otolaryngology, ophthalmology, and gynecology, the clinical material of the hospital provides opportunity for study and for acquiring a certain degree of proficiency in the diagnosis of cancer in its more common situations, and for the handling of early and doubtful cases, as well as in the radical operative treatment of the disease.

The student who selects a medical intern service attains experience in the diagnosis of some of the more common internal forms of cancer, such as that of the stomach, colon, pancreas, lung, and of the leukemias and lymphomas, but his opportunity for the study of cancer of other regions is more limited. A combined medical-surgical service is thus of advantage to the student who expects to enter general practice. Hospital services limited to one or another of the specialties give little opportunity for general experience and when possible should be taken only after a general medical or surgical or combined intern service, instead of as a substitute.

That the experience of the surgical intern service should warrant the graduate in holding himself out as qualified for special practice in

cancer surgery however cannot readily be agreed. It is wiser for him to continue active work as a general surgeon and devote such time as he may either to the study of cancer in the laboratory and in the roentgen ray and radium department, or in the cancer clinic rather than to attempt to specialize in cancer work exclusively at the end of his intern service. The broader training of the general surgical service for a number of years at least is greatly needed by the surgeon who is desirous of making of cancer the chief interest in his professional career. If he cherishes this ambition however he should appreciate that he must train himself with the definite objective of becoming one of a group of individuals who are united in the purpose of securing to the cancer patient the best service which modern medical science affords—whether as a surgeon or an internist, a radiotherapist or a pathologist, or a representative of one of the specialties he must develop first such general proficiency in his own line as to qualify himself to represent that department adequately in consultation with representatives of other departments similarly qualified. He must add to this special training of his own an adequate knowledge of and a sympathetic appreciation for the essential principles of the other departments concerned with the cancer problem, especially the three departments, surgery, pathology, and radiotherapy. By this training he should succeed in preparing himself to take a place among the constantly increasing group of physicians who recognize the necessity for providing more adequate medical resources for the relief of the vast numbers of individuals in the community afflicted with cancer.

To summarize we may say that

1 Improvement in the instruction given in the medical school to undergraduates on the subject of cancer is to be desired.

2 This is to be obtained by improvement of the quality of the instruction rather than by addition to the amount of time devoted to this subject in the curriculum.

STRIKE OF CITY HOSPITAL ANNEX WORKMEN

The large addition under way at the Boston City Hospital is suspended because of the strike of union building trades mechanics.

DRIVE FOR FUNDS FOR THE CAPE COD HOSPITAL

Because of extensive improvements at the Cape Cod Hospital at Hyannis a campaign for funds has been started. This hospital serves a population of 32,000 living within an area of 444 square miles and has eighty-three beds.

3 The chief defect in cancer instruction in medical schools today is the lack of correlation of the instruction given by many different departments in the schools and hospitals.

4 This defect is best overcome by the organization of cancer clinics for the group study of cancer cases in hospitals and by their use for teaching undergraduates.

5 Where cancer clinics are not in existence and cannot be organized in teaching hospitals, an attempt should be made to obtain cooperative and coordinated plans for teaching the subject of cancer from the departments especially concerned in this instruction, i.e., surgery and its specialties pathology and radiotherapy.

6 Every graduate of the medical school should obtain a general knowledge of cancer and in addition he should (a) recognize the supreme importance of early diagnosis (b) recognize symptoms which indicate even the possibility of the existence of cancer in its more common situations, and (c) know what steps are to be taken with safety to the patient in securing an immediate and positive diagnosis as to the presence of cancer and if cancer is present what steps are to be taken to procure the most effective treatment.

7 The surgeon who desires to make cancer the chief interest of his professional career requires a period of years of preparation by post graduate study and the actual practice of general surgery. During these years he should pursue the pathological study of cancer in the laboratory to the extent of his opportunities. Some training and experience in radiotherapy should also be acquired. The radiotherapist has the same need for pursuing the practice of his own specialty and should add the pathological training also while making himself familiar with the diagnosis of cancer and its surgical treatment. Only with this experience can he fit himself adequately to join the representatives of the other departments of the hospital in the group study of the patient in the special cancer clinic or the cancer hospital.

During the past year 1124 persons were admitted and 1758 out patients were treated.

The hospital is approved by the American College of Surgeons.

THE APPOINTMENT OF MRS. J. P. SIMONDS

Mrs. J. P. Simonds, 25 East Walton Place, Chicago, Illinois, has been appointed Chairman of Press and Publicity for the Woman's Auxiliary of the American Medical Association to succeed Mrs. Robert E. Fitzgerald who will next June, take office as President of the National Auxiliary.

CASE 21321

PRESENTATION OF CASE

First Admission A sixty-seven year old American housewife entered complaining of right upper quadrant pain

About twice a year during the past several years the patient had attacks of mild intermittent right upper quadrant pain associated with light stools, dark urine and jaundice, the latter appearing usually within twelve hours after the onset. The attacks, which occasionally began half an hour after eating, usually lasted a week, although the pain itself lasted only a day or two and was followed by marked weakness and toward the end by chills and fever. The pain at first radiated to the midscapular region but recently had remained localized to the right upper quadrant. There was no vomiting. Two months before entry she had a very severe attack lasting about two weeks and three days ago another which lasted until admission. At this time, in addition to dark urine, light stools and jaundice, she vomited but had no chills or fever. The pain was present at night as well as during the day. During the past three months she had lost about fifteen pounds in weight.

Her family, marital and past histories are non-contributory.

Physical examination showed a well-developed and nourished woman in no acute distress. The skin and sclerae were icteric. Her teeth were false. There were a few crackling râles at both bases. The heart was not remarkable. The blood pressure was 110/60. The abdomen was moderately distended. There was diffuse tenderness with spasticity in the right upper quadrant. The liver edge was not made out because of the tenderness. No masses were palpable.

The temperature was 100.2°, the pulse 92. The respirations were 18.

The urine was dark amber in color and had a specific gravity of 1.004 to 1.015, a very slight trace of albumin and a four plus test for bile. The sediment contained several white blood cells and an occasional epithelial cell. The blood showed a red cell count of 3,500,000, with a hemoglobin of 55 per cent. The white cell count was 13,000, 86 per cent polymorphonuclears. The stools were brown in color. The icteric index was 50, the van den Bergh 1.2 milligrams

The bleeding time was 3 minutes, the clotting time 9 minutes.

She was given one liter of 10 per cent glucose intravenously and on the fifth day, following a transfusion of 500 cubic centimeters, operation was performed.

The gall bladder was found enlarged, acutely inflamed and adherent to all the surrounding structures. Pressure on the gall bladder caused a slight amount of bile to exude from this area of inflammation. The gall bladder was opened and about fifty stones were removed. It was not possible to remove the gall bladder because of adhesions and extensive bleeding. The common duct was opened and forty-seven stones were removed from both the common and hepatic ducts. The latter were distended and easily admitted a finger on each side. Several stones were also removed from the ampulla, which was then dilated and several stones pushed through to the duodenum. A catheter was sutured into the common duct and the duct closed around it. A large tube was sutured into the gall bladder.

Following operation the temperature rose to 102° for a few days but soon returned to normal. Her jaundice improved. An icteric index on the fourth postoperative day was 20 and a van den Bergh 6.8 milligrams. She continued to do well and was discharged approximately three weeks after admission.

Second Admission, nine months later

Except for an occasional mild attack of abdominal pain without jaundice she felt perfectly well during this interval. She gained weight and had a sense of well-being. Two days before entry, following a heavy meal, she complained of intermittent cramplike epigastric pain followed by vomiting and the passage of dark-colored urine. Since then she vomited several times.

Physical examination showed a very sick woman with slight jaundice of the skin and sclerae. There were numerous moist fine inspiratory râles at the bases. There was spasm of the upper abdomen with a questionable area of fullness. There was tenderness below each costal margin, more marked on the left. The liver extended four fingerbreadths below the right costal margin. The blood pressure was 95/55.

The temperature was 98°, the pulse 118. The respirations were 25.

The urine was brown in color, contained bile and many white blood cells as well as numerous bacteria. The blood showed a white cell count of 25,000. The icteric index was 45. The non-protein nitrogen of the blood was 30 milligrams.

On the day following admission operation was performed.

DIFFERENTIAL DIAGNOSIS

DR BETH VINCENT This case is that of a sixty-seven year old woman who entered in an acute attack of biliary disease with a history of several years pointing clearly to disease of

the gall bladder and to gall stones. This supposition is confirmed by the findings at operation, which consisted of removal of all the stones that could be found with drainage of the common duct and simple drainage of the gall bladder but not a cholecystectomy on account of the poor condition of the patient. The convalescence was normal. In a sense this might be looked upon as the first stage of a two stage operation because in our experience most cases of this type do have recurrence of acute symptoms and require a final and radical operation to accomplish a cure. This is what happened in this case, the patient came in the second time in another acute attack.

We know that this patient has chronic disease of the gall bladder. She had had a great many small stones and the presence of jaundice suggests that one of the stones was overlooked and that she has obstructing stones in the common duct. She also has symptoms that point to the other complication that frequently occurs in these biliary cases, that of pancreatitis. In addition there is a rather large liver. The patient has had biliary disease for a long time and it is quite possible that she should show some cirrhosis, what we call obstructive cirrhosis in such cases. While all the cases of gall stones of long standing of course do not develop malignant disease it is true that malignant disease of the gall bladder and biliary tract is almost always preceded by gall stones and although there are no specific indications in this case we must always be prepared to find malignant disease in cases of gall bladder disease of this sort. I know that the operator found a chronic diseased gall bladder. He may have found stones obstructing the ampulla. I should think it highly probable that she showed some acute process in the pancreas and I expect that she may have some cirrhosis of the liver.

CLINICAL DISCUSSION

Dr. EUGENE M. DALAND: There were forty six stones taken out of the common and hepatic ducts. They were fairly large faceted stones. The hepatic ducts were dilated so that it was possible to insert the full length of the finger and shell out the stones, most of which were faceted and tightly packed. One thing that does not appear in the history is that at the first operation we definitely knew we had left some stones in the hepatic duct. We got out all we could and crushed several more which we could feel two or three inches up in the hepatic duct. We dilated the ampulla and after operation watched for passage of stones, but during the next four weeks no stones were passed.

This patient was a very feeble individual and having carried her through the first episode we did not dare to consider the second operation. She just barely made the grade the first time

and we did not think it wise to do anything in the interval. When she came in the second time she had tenderness in the upper abdomen, more marked on the left. We did not dare do anything for twenty four hours but then her white count rose from 25,000 to 44,000. We suspected that she had an acute pancreatitis and operated with that preoperative diagnosis. The previous operation was done through a right rectus splitting incision and the second was done through a midline incision, expecting to find something in the pancreas. The pancreas was normal—no thickening or other evidence of pancreatitis. We explored the gall bladder which was still enlarged but no stones were palpable. We opened the common duct, the bile there was under pressure and when the duct was opened it spurted three or four feet into the air. We drained out about a liter of bile at that time. As I remember, there were only two stones found in the common duct. The common duct and the gall bladder were drained.

She lived about a month after the operation. She drained well from the common duct. We could not get her to eat. We tried feeding her bile with some degree of success but half the time she refused it. She refused all sorts of fluids by vein or by vein and she refused a jejunostomy which we wanted to do. She failed quite rapidly. At the end of a month she did allow us to do a jejunostomy for feeding purposes but it was too late and she lived only a few days after that was done.

CLINICAL DIAGNOSES

Acute cholecystitis
Cholelithiasis

Dr. BETH VINCENT'S DIAGNOSES

Chronic cholecystitis
Common duct stone
Obstructive cirrhosis of the liver
? Acute pancreatitis
? Carcinoma of the gall bladder

ANATOMIC DIAGNOSES

Cholelithiasis, intra and extrahepatic
Acute fibrinous bronchitis with pseudo-asthmatic paroxysm
Cholecystitis, chronic
Operative wounds—cholecystostomy, choledochostomy, jejunostomy
Cirrhosis of the liver, obstructive
Icterus
Peritonitis, localized, acute and chronic
Leiomyomata uteri

PATHOLOGIC DISCUSSION

Dr. TRACY B. MALLORY: The autopsy showed a condition against which the surgeons were powerless. The entire biliary tract within the liver was filled with stones from end to end. We

did not count them but there must have been several hundred stones. They started in each hepatic duct, running up through every branch and as one got farther and farther out into the liver the stones became smaller and smaller. When one reached the finer terminal bile ducts the stones were almost microscopic in size, just a fine granular sand but there was not a duct within the liver that did not contain particulate inspissated material. This is a fairly rare condition. It has been claimed at times that gall stones are only formed in the gall bladder and if they are found in the hepatic ducts or in the liver they are supposed to have regurgitated from the gall bladder. I think cases such as this patient of Dr. Daland's provide strongly suggestive evidence that that is not the case. The gall bladder in this woman was rather thin walled, not markedly injected, and I find it inconceivable that all these stones were formed in the gall bladder. I think they must have formed locally in the liver. As would be expected with a high grade and long-standing biliary obstruction, the liver showed marked secondary changes. There was a very chronic well-marked biliary cirrhosis. There was also an acute terminal central necrosis so that an element of liver insufficiency might well have come in at the end.

A rather surprising terminal picture was the lungs which were acutely distended and looked exactly like the lungs of a case of bronchial asthma. On section, however, all the bronchi were found filled with plugs of polymorphonuclear leucocytes and fibrin,—no eosinophiles and no mucus. I believe she developed the equivalent of an asthmatic paroxysm because of diffuse bronchial obstruction from fibinous bronchitis. I have seen a similar picture in fatal pulmonary hemorrhage where casts of clotted blood obstructed the entire bronchial tree. There was no pneumonia, and in spite of the multiple operations there were relatively few adhesions, except in the right upper quadrant, and no signs of intestinal obstruction. There was a little localized peritonitis beneath the second gall bladder wound.

DR. DALAND. She had an attack of asthma three or four days before death which responded to adrenalin.

DR. MALLORY. I think there is no question that this terminal event was closely related to asthma but certainly not ordinary bronchial asthma.

CASE 21322

PRESENTATION OF CASE

A seventy-eight year old unemployed Maine carpenter entered with the complaint of vomiting of two months' duration.

The patient had always had a little indigestion with a tendency to belch and gag easily. Three or four months before admission this

became worse but he had no pain or vomiting. Two months before admission he began to vomit fairly frequently, usually one to two hours after meals. The vomiting was preceded by nausea but there was no pain. The vomitus consisted of food and occasionally small amounts of blood. He began to lose weight and to grow weak. For the past few weeks he had been unable to retain any solid food. He had been able to keep down one or two small egg-nogs and a few glasses of water each day. For the past five days however, he was unable to keep anything down. At no time had he complained of pain. There had been no massive hematemesis. Five days before admission he was forced to go to bed. He noticed at that time that his urine was dark. His son believed that his color had been poor although he was not certain that it had been yellow. About one week before admission his right leg began to swell and, within the past few days, enlargement of his abdomen was noted. He had been somewhat constipated during the past few weeks.

For the past twenty years he had drunk all sorts of alcoholic beverages and according to his daughter was moderately intoxicated fairly frequently. His family and past histories are otherwise irrelevant.

Physical examination showed an elderly, slightly jaundiced man with shallow and rapid respirations. He complained of some pain and numbness in his right leg. There was areolar edema. The pupils were equal but slightly irregular. They reacted sluggishly to light. There was a cataract on the right. The fundus on the left showed moderate sclerosis of the vessels. The teeth were extremely dirty and carious. In the left supraclavicular fossa there was a firm slightly movable nodule 2.5 centimeters in diameter. The heart was slightly enlarged. The sounds were regular, faint and of poor quality. There was a questionable gallop rhythm. The blood pressure was not obtained. The apex rate was 90. The lungs showed dullness and suppressed breath signs at the left base posteriorly to 3 centimeters above the angle of the scapula. The abdomen was distended, with dullness in both flanks and a fluid wave. There was some tympany in the right flank. In the right upper quadrant there was a firm nodule 3 centimeters in diameter. In the midportion of the upper abdomen there was an indefinite hard ballotable mass. Peristalsis was present. The right leg was swollen as far up as the groin, and was blue tender and cold. Rectal examination was negative.

The temperature was 99.6°.

Examination of the blood showed a red cell count of 4,600,000 with a hemoglobin of 70 per cent and a white cell count of 25,700, 96 per cent polymorphonuclears.

The patient was put to bed and given two

doses of one sixth of a grain of morphia. At 1 15 a.m. on the second day the nurse found him dead in bed.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD H. SWEET: This is an elderly person who comes in with a story which sounds like pyloric obstruction. We know that the first symptom was vomiting. He had had some indigestion but he had had it most of his life and therefore we do not attach much significance to it. About two months before he entered the hospital he began to vomit quite frequently. The vomiting came usually two hours or so after meals which would tend to suggest ulcer or some other trouble in the region of the pylorus. As we read along we learn that the vomitus consisted of food and occasionally of small amounts of blood which suggests a bleeding lesion in the stomach although one might get bleeding because of the vomiting. It is however suggestive of ulcer or of a carcinomatous growth in the stomach. Then we find that whereas at first he was able to take solid food he goes through a period when he can take only soft foods until he finally reaches the point where he vomits even fluids so that we have a clearly progressive upset of the stomach. Then another symptom arises five days before admission. The urine becomes dark in color and there is some question as to whether he has slight jaundice. Finally, he noticed a swelling of the right leg and also a rather recent swelling of his abdomen.

Thinking back over the history it seems to me that it fits best of all some lesion of rather rapid development which has obstructed the pyloric outlet to the stomach, probably carcinoma. One might question that diagnosis as an explanation of jaundice but one not infrequently sees involvement of the common duct with a carcinoma of the stomach. We are told that he had been a heavy drinker most of his life and was intoxicated fairly frequently which makes us wonder if he had cirrhosis since he had jaundice and vomited blood. But to me the story sounds more like an obstructed stomach.

In the physical examination we find that he had mild jaundice, pain and numbness. An interesting finding is the firm hard nodule above the left clavicle. When we are dealing with people who we suspect might have carcinoma of the stomach we always feel in the left supraclavicular fossa because years of clinical observation have shown that many cases of carcinoma of the stomach show a metastatic lymph node in that region. The cardiac condition apparently was not very satisfactory but he was seventy-eight years of age. We do not know whether they made an effort to obtain the blood pressure.

There are some signs in the lung which I am not able to interpret.

The abdominal examination suggests that he had ascites. Then we discover that he has two abdominal masses, one in the right upper quadrant 3 centimeters in diameter and another in the upper epigastric region which is described as being indefinite, hard and ballotable, I suppose because of the presence of fluid. There was peristalsis.

The red count showed no particular anemia although the hemoglobin was 70. The polymorphonuclears might have been dependent on a pulmonary condition if he had pneumonia.

As I see this case, it seems to me that one can explain the entire picture on the basis of carcinoma of the stomach with perhaps a metastatic nodule in the liver and a metastatic lymph node above the clavicle, and also as I have said, it is not beyond the realm of possibility to explain the stenosis of the common duct by direct invasion or by extension or pressure from a neighboring involved lymph node. There is this to say, however, that we not infrequently see a carcinoma of the pancreas which will give a similar train of symptoms. I know of one surgeon who has said—I do not know how he feels about it now—but he has said that in doing a cholecystoduodenostomy for obstruction of the common duct from carcinoma of the pancreas it was rational to do a gastroenterostomy as well because so many cases, if they live long enough would develop obstruction of the pyloric end of the stomach as well. We have here the supraclavicular node and I do not believe that is found so often with carcinoma of the pancreas. It seems to me that the train of events is more in favor of a primary lesion in the stomach than a secondary one.

DR. WYMAN RICHARDSON: I wonder how Dr. Sweet accounts for the cold blue leg?

DR. SWEET: I meant to speak of that. I think we often see in terminal malignant disease, swelling and edema of the leg and sometimes venous obstruction from involvement by metastases of the pelvic portion of the abdominal cavity. I think that that might possibly have something to do with the edema and swelling of the leg. The ascitic fluid is undoubtedly due to peritoneal metastases.

CLINICAL DIAGNOSIS

Carcinoma of the stomach with metastases to the liver and the peritoneum.

DR. RICHARD H. SWEET'S DIAGNOSES

Carcinoma of the stomach with abdominal carcinomatosis and obstruction of the common duct by malignant disease.
Metastasis to supraclavicular node.

ANATOMIC DIAGNOSES

Carcinoma primary site undetermined, ♀ gall bladder.
Hematocele in gall bladder.

tions conducted by the Massachusetts Board and of this number forty-six (more than fifty per cent) are graduates from nonapproved schools in Massachusetts. Only four came from Class A institutions in this state.

The situation is deplorable in that the Old Bay State continues to be indifferent concerning the quality of medical education carried on within its borders. In comparing this last with previous reports, the situation does not indicate that the unaccredited schools are raising their standards and the inference is warranted that either the schools from which the rejected candidates come do not adequately prepare students to meet the standards adopted by the examining board or that the matriculants in these substandard schools are not intellectually fitted to profit by the instruction given.

Either of these hypotheses should arouse the interest of the citizens of this Commonwealth because it is unfair for a school to accept the price of tuition from students without giving to a reasonable degree, that which is sought. Neither is it right to encourage a young person to engage in an occupation for which he may not have the essential qualifications for success. There are already too many misfits in medicine. The specious argument that these substandard schools open the only way for the poor youth to enter professional life is not true for rarely do such institutions give any material assistance in enabling the needy student to meet the cost of living during the required four years of study.

On the other hand the better-class medical schools take an especial interest in capable students and provide needed assistance thereby generally insuring the completion of the scheduled courses of instruction.

In the early years of this century there were many commercial medical schools. Fortunately most have been driven from this field for it is well known that under present conditions the student fees cannot support a high-grade medical school.

The pertinent question before us is what is the matter with Massachusetts? Since all other states in the Union have gone beyond this Commonwealth in conferring authority to registration boards relating to the standing of medical schools, the situation is deplorable. The only explanation seems to be that there is no adequate appreciation of this situation throughout the state and, since it is fundamentally an educational problem relating to public health, the responsibility rests squarely with the medical profession.

Organized medicine has been emphasizing the responsibility of the doctor in disseminating information respecting the etiology and treatment of disease. It has done little effective work in Massachusetts in convincing the public of the benefits incident to a uniformly well-trained medical profession. At the present time

this is the great opportunity of the profession to show its devotion to the common welfare. If aroused and directed, the Massachusetts Medical Society could lead the electorate to demand of its legislature equal standing with her sister states.

A MORE COMMON EMERGENCY IN SUMMER

EVERY general practitioner should read the letter contributed by Dr. Alexander Marble which appears on page 285 and especially physicians who care for children with diabetes.

Delay is dangerous in hypoglycemia and the inclusion in the doctor's emergency outfit of the properly constructed syringe and ampules put out by some dealers will give assurance of efficiency in dealing with this emergency. Every case of coma in a new patient calls for a differential diagnosis of the condition which may be responsible for this symptom.

MISCELLANY

TO PRESIDENTS AND SECRETARIES OF STATE ASSOCIATIONS AND DELEGATES TO THE AMERICAN MEDICAL ASSOCIATION

Important!

Information coming to the Committee indicates that the action of the House of Delegates at the Atlantic City Session in consideration of Sick-ness Insurance has in some instances not been fully understood. The misconception has to a degree been advanced by reports in some journals and headlines in public newspapers to the effect that sickness insurance has been given broad approval by the American Medical Association. Some groups are said to have planned to act on this exposition.

The report of the Reference Committee of the House of Delegates has been published in the Journal and the Special Report of the Bureau of Medical Economics will soon be available to members of the Association. It is urgently recommended that both the Special Report of the Bureau of Medical Economics containing an analysis of the various plans at present in operation and the report of the Reference Committee which were adopted by the House of Delegates be carefully studied before any plans are considered. No county society should consider the creation of any new social machinery for the extension of medical service or collection of compensation for such service before the existence of a real need for such change has been demonstrated and the requirements and available existing facilities have been carefully appraised. The report of the Committee states that "Analyses show that the class for which special provision is necessary is far smaller than most lay writers and the results of so-called surveys would indicate." The economic problems of the individual cannot be adequately dealt with on the basis alone of his classification in the group of those who receive low incomes. Social workers have accordingly long recognized the necessity of the investigation of the problem of each individual. Upon this basis is the method of individual study or "case work" of social service founded. The problem of needed medical service to each person of the group is also an individual one, and one which cannot be met by group classification.

Based upon an investigation of the resources of the individual, an adjustment of fees for needed

medical services according to ability to pay in graduated installments in most instances meets the problem of the individual patient who is not wholly indigent. It is to this type of organization that the Legislative Committee referred in a previous communication as meeting public and individual requirements. If the individual is indigent, he obviously cannot be expected to pay for medical service on an adjusted fee basis nor is he provided for in proposed sickness insurance or any plan other than charitable or direct Government indigent relief. In that instance medical costs are only one phase of the individual's economic distress, and his problem requires more comprehensive measures than simple provision of medical services.

A group purchasing an undetermined amount of medical service upon a prepaid fixed premium basis offered to all within broad income limits who apply sooner or later will include a large percentage of individuals who can and have previously supported medical practice upon normal private basis. Experience has shown that prepayment medical service has not been salable on the basis of adequate fees for the physician as evident in experience here and abroad.

Some of the effects of such plans are as follows: (1) A large amount of medical work will be done on a financial basis which is inadequate to provide for maintenance of proper standards. (2) Those not included in the plan will be educated to demand medical services at correspondingly low fees. (3) The operation of such plans over a period of average conditions will not add to the sum total of fees derived from the income group insured, and aside from possible temporary changes in distribution will simply reduce more professional services to an inadequate financial basis. (4) The establishment of such plans will create a pattern which, although undesirable, it may be impossible to change or discard and may therefore lead to still broader adoption of objectionable practices. (5) There is reason to believe that some local plans even though now apparently satisfactory inherently possess the same weaknesses and destructive tendencies as have been evident in similar patterns of operation in foreign countries. (6) The questions of contract practice, legal responsibilities and state insurance regulations encountered as well as the drift to solicitation of patients and violation of medical ethics cannot be presented here. (7) Extensive systems of voluntary sickness insurance invite competitive offerings by irresponsible people, and in Europe have created conditions so chaotic as to advance the establishment of compulsory insurance by legislative act.

Less populous communities in which the medical and financial needs of the individual patients are known to physicians and public relief officers have no need of any cumbersome machinery.

It is to be noted that the action of the American Medical Association did not contemplate the operation of any plans, except by local constituent societies of the American Medical Association and that in so doing medical societies must be guided by the

Ten Fundamental Principles adopted in June, 1934

All proposed plans of county societies should be submitted to officers and appropriate committees of state medical societies. Before considering any program, it would also seem advisable to confer with the Bureau of Medical Economics of the American Medical Association which has the greatest opportunity to study the needs for any varying successes of the existing experiments.

Great responsibility rests upon state and local medical organizations and upon Delegates, who entered into the consideration and adoption of these reports, to see that the action of the House of Delegates be not construed as approving or encouraging the es-

tablishment of local sickness insurance units embracing the objectionable features against which the profession, as a national body, is making such a determined and effective fight.

CORRESPONDENCE

A PLEA FOR DOCTORS' PENSIONS

July 20, 1935

Editor, *New England Journal of Medicine*,

It is with a sense of shame and deep mental anguish, that I read the editorial in this week's *Journal* and Mr Hobbs' letter explaining the conditions under which the ERA aid is offered to indigent physicians in our state, and the clause which excludes the unfortunate recipients of such aid, in case any member of his family earns from \$10.00 to \$20.00 a week, is adding insult to injury. That so bountiful a sum, brought in by some young son or daughter of an unfortunate physician should be considered sufficient to sustain the needs of one who has given so much of himself to the community, in itself speaks for the sweetness of charity.

But, that a society of 160,000 men and women of a proud and most useful profession should come to a pass, where some few hundreds of its members should be left in such misery, is even more painful.

I, therefore, respectfully submit to you for publication, a letter which I sent some time ago to our most esteemed *A M A Journal*, that so loudly proclaims itself sufficient to care for the profession in all its phases. Needless to say, my letter was not published because the trustees of our great American Medical Association could not be bothered with such trifles as the welfare of its members.

Since I wrote that letter, the crying need for some substantial and mutual aid has certainly increased manifold. The letter is self-explanatory and I hope that our members will see the soundness of the plan.

Very truly yours,

256 Bennington Street,
East Boston, Mass

R GURALNICK.

COPY OF DR GURALNICK'S LETTER TO THE AMERICAN
MEDICAL ASSOCIATION

October 24, 1934

Editor, *American Medical Association Journal*,

In speaking to a patient friend of mine the other day, a letter carrier by occupation, and a man in the sixties, I was surprised to learn how well they are taken care of on retiring, by means of an old age retirement fund. According to the information I received from him, by withholding three per cent of his earnings through the period of his employment, the government is able to pay him one-half of his wages upon retirement, and not only that, but at the age of sixty-three or thereabouts, retirement is compulsory, thus creating a job for a younger man.

On the other hand, it is no more a secret that a good many members of our organization, who are of advanced age, are at present on welfare lists. Boston alone has thirty such recipients. The number, however, must be infinitely greater only they are too proud to ask for aid.

I have spoken to many physicians about an old

age retirement fund and everybody seems to agree that the time has come when something should be done in this direction. It appears that with all our constant worries about giving better services to our patients and with our latest philanthropic inclinations to give those services at remunerations bordering on gratis, we ourselves are rapidly approaching the proverbial "Forgotten Man".

It is shameful to think that a profession consisting of about 160,000 men and women, one hundred thousand of whom are members of the A. M. A. (I am sorry I do not know the exact number) that with so large a membership, nothing has been done to provide such a fund which could easily have taken care of the few, that through old age find themselves in need of financial aid. With a fund of this sort, they could retire and live in comparative ease the rest of their lives. *Incidentally, the younger members of the profession would profit by such an arrangement.*

I realize that to establish such a retirement fund is fraught with difficulties, but such difficulties could be overcome, and the A. M. A. seems to be the only logical organization to take the necessary steps. *Again, a fund of this kind would rapidly increase in amount, through voluntary contributions and bequests of the more fortunate members of the profession, who at present divert such sums into other channels.*

At a payment of let us say, ten dollars a year per member, into the treasury of the A. M. A., within a short time a sufficient sum would accumulate so that any beneficiary wanting to retire at the age of sixty or thereabouts, would be assured of an income of about \$2000 a year, which amount should be sufficient for one to live in comparative ease.

This does not mean, however, that anyone would be asked or expected to retire at the above-mentioned age. *Retirement would be entirely voluntary* and the benefit extended to only such members as would have no other source of income, and only upon the complete surrender of the rights to practice in any remunerative or competitive capacity. On the other hand, membership in the various societies and the academic interest in medicine would still be one's privilege.

The scope of activities of the A. M. A. would undoubtedly be enlarged, and the membership would come to the realization that something substantial is at last being done by the organization.

R GURALNICK

CHIROPRACTIC VERSUS CHIROPRACTICE

Editor, *New England Journal of Medicine*,

What a hideous word this "Chiropractic"! In English "ic" is usually an adjective suffix and the only way of making a noun of such an adjective is by adding the definite article as e.g., "That's the chiropractic in it".

But there is a fine word for them! Perhaps a century ago the "practice" of medicine was the "Praxis". There are some other similar Greek

words. Thus we have kept 'Sepsis' but have en-
planted 'Skepsis'. So there you are Mr Chiro-
practor! Say that you practice Chiropraxis or
Chiropraxy.

And so, according to this new law that your Edi-
torial quotes the definition reads adjustment
by hand only. Just this very day a patient is tell-
ing me of a Chiropractor jumping on the back. Said
he witnessed it.

All this manipulating tribe have always assumed
an exceptionally erudite knowledge of anatomy to
the disparagement of physicians. I had a youthful
aspirant, as a patient who had had this idea
pumped into him. There he was attending the
'Massachusetts College of Osteopathy' (same
brood!) housed in two three-storied brick dwelling
houses up on Huntington Avenue with the sign
(blue?) paraded quite across them. And within a
stone's throw the new Harvard Medical School with
its century of tradition facilities and museum.
What is worse the *Boston Transcript* gave them an
Editorial echoing this claim.

It has always seemed to me that the very phi-
losophy of their craft underwent spontaneous disin-
tegration. Pretty much all things caused by pres-
sure on the posterior roots as they pass through
the foraminal Enquire n moment. So well protect-
ed are these roots that, except in the case of a
diseased bone or very slack ligaments nipping is
impossible. Have they dissected a chicken's neck?

The spine elongates can turn in the cervical and
lumbar regions but even then maintains its rela-
tive adjustment of vertebrae. For the most part
the dorsal region is a fixed column except for
elongation. The cervical region they can play with
to their heart's content. A young patient of mine
attending one of their clinics saw stars and dropped
to the floor. The relations of the atlas and axis
were plainly disturbed (examination) and she could
not turn her head for months. They were well
scared. Dr Douglas Graham reported several such
cases.

And furthermore how inaccessible to manipu-
lation is the major part of a vertebra. The triangular
space between spinous and transverse processes is
filled up with strong muscular tissue and the bodies
of the vertebrae at a depth of two or perhaps more
inches. One cannot manipulate the spine much or
relieve pressure on the deep lying lateral roots by
wiggling spinous processes, whether by hand or by
foot. The spine really should be approached from
in front, which of course, speaking by and large is
impossible.

I think it to be a pity that, in a weak spirit of
Catholicity many men adopt an indulgent attitude
toward this third generation, Chiropraxis. All
claims for cures (with which the public is fairly
bursting) we doctors ought to know should run the
gauntlet of logical investigation so great is the op-
portunity for coincidence, false data, and the opera-
tion of credulity.

THE TENDENCY TO HYPOGLYCEMIC ATTACKS IN SUMMER

July 31 1935

Editor *New England Journal of Medicine*,

For most people — young and old — the summer
time is a season of added physical activity. The
average person is able to spend much more time out-
of-doors exercising at work or at play. The mod-
ern, well-controlled diabetic approaches the normal
so closely that practically all types of activity are
possible for him. This is fortunate because exercise
can and should be used to the fullest extent in treat-
ment. That exercise increases the blood-sugar low-
ering effect of insulin is well recognized.

Because of this beneficial effect, diabetics are
apt to do better in the summer time. Temporarily
tolerance for food is often increased and need for
insulin lessened. Unless physicians are on the
watch for this and take care to decrease dosages of
insulin (as indicated by tests of urine and blood)
severe insulin reactions may occur. We have had
this fact impressed upon us recently by the remark-
able reductions in dosages which have been possible
with diabetic children in summer camps. Until
stabilization on the new level is secured, hypo-
glycemic attacks may be frequent unless the physi-
cian and patient take care to avoid overdosage with
insulin.

We have found it helpful on many occasions to
have at hand a suitable syringe and needle and am-
pules containing 20 cc. of 50 per cent glucose prop-
erly buffered for intravenous use. Particularly in
children insulin reactions may be sudden and se-
vere and at times may result in unconsciousness. In
such a situation the anxious parent or attendant
may experience great difficulty in getting the child
to open tightly-closed jaws or to swallow orange
juice or even syrup. For a child to remain in hypo-
glycemic coma for hours is without doubt a potential
source of danger to the integrity of nervous centers.
To relieve the condition promptly the physician
should be equipped to give glucose intravenously.
Usually 20 cc. of 50 per cent glucose suffices for im-
mediate return to consciousness. As a second heat
epinephrine, 1/1000 may be given subcutaneously
in dosage of 0.5 cc. and followed by carbohydrate
orally when sufficient return to consciousness has
been obtained.

Since reactions are most apt to occur in the late
forenoon, mid morning lunches of from ten to twenty
grams of carbohydrate should be the rule for diabetic
children in summer camps. Particularly if this
lunch is not taken, swimming and horseback rid-
ing should not be engaged in during the latter part
of the morning by a child whose blood sugar is
known to fluctuate easily. Likewise for adults who
take sizable doses of insulin a mid morning lunch
is advisable if strenuous exercise or driving an auto-
mobile is planned for the latter part of the fore-
noon.

This letter is written not to present new facts but
to call attention to the need for careful supervision

of the diabetic who at this season is leading a much more active life than is usual for him

Yours very truly,

ALEXANDER MARBLE, M.D

81 Bay State Road,
Boston, Mass

RECENT DEATHS

BRYANT — FREDERICK BRYANT, M.D., of 858 Main Street, Worcester, died at Hull, Mass., July 29, 1935, after an extended illness.

He was born in Montville, Maine, in 1871, the son of Alonzo and Ariadana (Bean) Bryant. He graduated from Colby College in 1905 and from the Harvard Medical School in 1910.

He was a Fellow of the Massachusetts Medical Society and the American Medical Association, also of the Harvard Club of Worcester and the Boston Medical Library.

Dr Bryant is survived by his widow, Mrs Mary Bryant, and a son, Frank Bryant, of Worcester.

BUTLER — DAVID MATHEW BUTLER, M.D., of Cambridge, with an office at 371 Commonwealth Avenue, died at the Cambridge Hospital, August 1, of injuries caused by an accident.

Dr Butler was born in 1890, graduated from the Brockton High School, and later from the Tufts College Medical School in 1915. He practiced in Brockton for several years and after preparing him self for special work in eye, ear and nose diseases opened an office in Boston.

He was a Fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his mother, Mrs Annie S Butler, of 12 Bassett Road, Brockton, and two sisters, Mrs Charles A. Weiner and Mrs Joseph Stone, both of Brockton.

HANLEY — FRANÇOIS JOSEPH HANLEY, M.D., of Whitman, Massachusetts, died suddenly, August 2, 1935. Dr Hanley was born in Hinsdale, January 10, 1869. After a premedical education at Monson Academy, Georgetown University, he entered Jefferson Medical College and graduated in 1893 and settled in Whitman the following year.

During the war he served at Fort Oglethorpe, Georgia, with the rank of Captain. He was a Fellow of the Massachusetts Medical Society and the American Medical Association, and was a member of the Hatherly Medical Association.

He was affiliated with the M C O F and Whitman Council, K. of C., and was a former trustee of the Whitman Town Library.

He is survived by his widow, Mrs Mary Hanley, and two sons, Dr F J Hanley of Whitman and Edward J Hanley of Schenectady, New York.

KEEFE — JOHN W KEEFE, M.D., of Providence, R I, aged seventy-two, died at his summer home at Narragansett Pier, August 4, 1935. He was well

known in Massachusetts and was a member of the New England Surgical Society, the American Society of Obstetricians, Gynecologists and Abdominal Surgeons, and other scientific bodies.

He was a former President of the Rhode Island State Medical Society, a Fellow of the American College of Surgeons and the American Medical Association.

NOTICE

REMOVAL

JOSEPH DANIEL FERRONE, M.D., announces the removal of his office to 860 Beacon Street, Newton Centre, Massachusetts.

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING MONDAY, AUGUST 12, 1935

Wednesday, August 14—

112 M. Clinico-Pathological Conference Childrens Hospital.

Saturday, August 17—

*10-12 Staff rounds at the Peter Bent Brigham Hospital

*Open to the medical profession

†Open to Fellows of the Massachusetts Medical Society

August 29 September 5—Latin American Congress of Physical Therapy, X-Ray and Radium. For information address Dr Madge C L McGuinness, 1211 Madison Avenue, New York City.

September 5, 6, 7—American Congress of Physical Therapy will meet at the Hotel Kansas Citian, Kansas City, Missouri. Program and circular of information may be secured by addressing American Congress of Physical Therapy, 30 North Michigan Avenue, Chicago, Illinois.

September 17, 18, 19—Eleventh Clinical Congress of the Connecticut State Medical Society. For details address Dr Creighton Barker, 129 Whitney Avenue, New Haven, Conn.

October 7-10—American Public Health Association will meet in Milwaukee, Wisconsin. For information address the American Public Health Association, 50 West 50th Street, New York City.

October 21-November 2—1935 Graduate Fortnight of the New York Academy of Medicine. See page 898, issue of May 9.

October 28-November 1—The Twenty-Fifth Clinical Congress of the American College of Surgeons. See page 1065, issue of May 30.

BOOK REVIEW

Researches Published from the Wards and Laboratories of the London Hospital During 1934. London H. K. Lewis & Co., Ltd. Price 7s 6d.

The collected papers of researches published from the London Hospital during 1934 continue, as they have in years past, to set a high standard. Of particular importance in this volume are the following papers: B F Byrom on "The Nature of Myxoedema", Hugh Cairns and Charles Donald, "The Diagnosis and Treatment of Abscess of the Brain", William Evans and Clifford Hoyle, "The Prevention and Treatment of Individual Attacks of Angina Pectoris", Otto Leyton, "Multiglandular Disease", and Janet M Vaughan on the anemias. With such a volume at hand, much that might be missed in the diffuse medical literature of the time is easily available.

NUMBER 7

VOLVULUS OF THE CECUM

Acute and Chronic With Reports of Eight Cases

BY RICHARD H. SWEET, M.D.*

VOLVULUS of the cecum as one of the causes of acute intestinal obstruction has been recognized for many years. According to Faltin the first case report was by Rokitsky in 1841, but no thorough consideration of the subject appeared until Ziegler and Manteuffel in 1893 published the first study of the condition. Since then many articles have appeared, most of them presenting case reports and several giving thorough discussions of the etiology, symptomatology and treatment. In all, several hundred cases have been reported, mostly in the foreign literature. In the experience of a single surgeon, however, cases of volvulus of the cecum must be relatively rare. The truth of this assumption is suggested by the fact, in the first place, that there appear in the records of the Massachusetts General Hospital (not including the author's two cases here reported) only six cases of volvulus of the cecum. Secondly, of these only two were operated upon by one surgeon, the other four having been treated by four different operators.

All of these cases and in fact almost all of those reported in the literature were of the acute type with total obstruction of the bowel and its attendant acute symptoms necessitating emergency surgery. There is, however, a type of subacute or chronic partial volvulus of the cecum which has been discussed by others, notably Jacobsen and Trueman, and which is illustrated by one of the cases to be presented here. It is because of this relative rarity of the disorder and especially because of the opportunity to present for comparison two cases representing the two clinical types that this report is submitted.

ACUTE VOLVULUS OF THE CECUM

The diagnosis of volvulus of the cecum is rarely made before operation or autopsy. As a result of this, many cases of partial volvulus producing transient attacks of complete obstruction with quick spontaneous relief occur without recognition. This fact is amply borne out by reviewing the reported case histories, many of which give evidence of repeated less severe attacks over varying periods of time before the serious total obstruction which brings the patient to operation or the autopsy table. The re-

sult of this is an abundant knowledge of the acute severe, emergency cases and relatively little knowledge of the chronic recurring type.

As a cause of acute intestinal obstruction, volvulus of the cecum is undoubtedly relatively infrequent. The American writers, Pratt and Faltin state that volvulus of the cecum makes up 5 to 6 per cent of all cases of intestinal obstruction, but this figure seems unduly high. For example at the Massachusetts General Hospital from 1873 to 1930 there were 520 cases of acute intestinal obstruction exclusive of those resulting from strangulated external herniae. Of these, six were due to volvulus of the cecum. This means that out of all cases of obstruction not including strangulated herniae 1.15 per cent were due to volvulus of the cecum. In marked contrast European writers on the subject almost uniformly quote much higher percentages. For example Jacobsen out of fifty-three cases of acute ileus, exclusive of herniae, finds volvulus to be the cause in 36 per cent. And of these 36 per cent due to volvulus the distribution of cases according to the portion of the intestine involved was as follows:

Volvulus of the cecum	4* per cent of all cases of volvulus.
Volvulus of the sigmoid	11 per cent of all cases of volvulus.
Volvulus of small gut	47 per cent of all cases of volvulus.

In other words, according to Jacobsen, volvulus of the cecum is the cause of 1.16 per cent of all cases of acute intestinal obstruction exclusive of strangulated external herniae as opposed to 1.15 per cent in the Massachusetts General Hospital series.

Analyzing the Massachusetts General Hospital cases in the same way one finds that of 520 cases of acute intestinal obstruction exclusive of strangulated external herniae there were fifty-three cases of volvulus and of these there were

Volvulus of the cecum	6 cases
	11.3 per cent of all cases of volvulus.
Volvulus of the sigmoid	10 cases
	18.8 per cent of all cases of volvulus.
Volvulus of the small gut	36 cases
	67.9 per cent of all cases of volvulus.

Although volvulus of the cecum seems to be

*Sweet, Richard H.—Assistant Surgeon, Massachusetts General Hospital and Palmer Memorial Hospital, Boston. For record and address of author see "This Week's Issue," page 322.

rather a common cause of intestinal obstruction in Europe it would seem that in this country as suggested by the series here presented it is an infrequent occurrence and that furthermore it is the least common form of volvulus

In the card index of the records of the Massachusetts General Hospital which extends as far back as 1873, there appear six proved cases of acute intestinal obstruction resulting from volvulus of the cecum. To these a seventh is added here, making in all only seven cases during a period of fifty-seven years in a large hospital clinic. Brief reports of these cases are as follows

CASE 1 E J A Aged forty eight years, married, colored laundress

Admitted October 18, 1906

Present Illness Two days before entry the patient was seized with generalized colicky pain in the abdomen followed by diarrhea and bloody stools. She vomited once. On the day of admission the pain became localized in the right lower quadrant and opposite the umbilicus where it was quite severe.

Physical Examination Temperature 98.6°, pulse 96. The tongue was moist but coated. The abdomen was distended and tympanitic everywhere. Every few minutes a mass became visible in the right lower quadrant (4 x 3 inches in diameter). This mass was tympanitic on percussion. There was visible peristalsis accompanied by severe pain.

Past History During the past ten years she had had frequent attacks of abdominal pain with constipation followed by diarrhea and the passage of blood and mucus. These attacks occurred at intervals of one or two months and lasted about two days.

Operation Ether anesthesia

"A left rectus incision was made. A much distended purple colored loop of intestine presented. Exploration showed this to be the cecum which had a very long mesentery. The lower end lay against the spleen. The entire cecum was twisted upon itself. The cecum and terminal ileum were resected and a Mixer tube was inserted in each end of the bowel and these brought out through the wound. The wound was drained. Condition at the end of operation poor."

Course The patient died on the evening of the fifth day of what appears from the text of the record to have been peritonitis.

CASE 2 S B B Aged sixty two years, male, white, married "filer"

Admitted December, 1908

Present Illness There was no antecedent history preceding three days before entry when he began with sharp abdominal pain, recurring ever since and associated with vomiting. His bowels failed to move in spite of several enemata. The pain was severe enough to require morphine.

Physical Examination The patient lay in bed with knees drawn up. His tongue was dry and coated, his breath foul. The abdomen was tympanitic everywhere with asymmetrical right sided meteorism, no mass was felt. Tenderness was evident on pressing over the right side of the abdomen.

Operation Ether anesthesia, median incision

There was a small amount of clear fluid. There was a portion of large bowel presenting which was distended and reddened, the diameter being about three and one-half inches. This was found to be the cecum which had undergone a volvulus of two and one-half turns. Detorsion of the cecum was done

and a Mixer tube cecostomy was performed through a right lower quadrant stab wound. A large amount of gas and fluid was evacuated.

Course There was a good recovery, but the patient died on the sixteenth day of pulmonary embolism.

Autopsy A fibroma of the colon was found at the point where the volvulus occurred. The cause of death was pulmonary embolism.

CASE 3 M R Aged forty eight years, female, white housewife

Admitted in 1911

Past History (1) In 1907 the patient was operated upon for acute intestinal obstruction for which an enterostomy was done and a Mixer tube put into the sigmoid which was found to be twisted. (2) In 1908 an exploratory laparotomy was done and a volvulus of the sigmoid found. This was corrected and a colostomy done. (3) Three months later the colostomy was closed.

Present Illness The patient had not had a bowel movement for five days before entry. The night before entry she had severe abdominal cramps. Glycerine and turpentine enemata were given without result. Next morning she was seen at the Out Patient Department where she was given a dose of magnesium sulphate solution (oz 1½). Six hours later she was brought into the hospital in collapse.

Physical Examination There was marked tympanitic distention of the abdomen. Temperature 97.6°, pulse 88. An enema was given without results.

Operation Ether anesthesia

The cecum was found to be distended and "as large as a fire hose." A cecostomy was done using a Mixer tube which was brought out through a lateral stab wound.

Course The patient recovered but continued to evacuate her bowels by cecostomy only. Six weeks later a second operation was done and the terminal ileum was sutured to the sigmoid and the ends of the isolated colon between the ileum and the ileocolostomy, were brought out through the abdominal wall. The patient recovered and was discharged with bowel function restored to the normal channel but with two intestinal fistulae from the isolated loop of colon. Nothing appears in the record about the final outcome of this case.

CASE 4 Male, aged 48 years, white shipper

Admitted in 1911

Present Illness There was a history of four days' duration beginning with griping abdominal pains which continued. On the evening before entry he vomited. There had been frequent hiccoughs. His bowels had not moved since the onset of pain.

Physical Examination The patient appeared quite ill and was suffering from severe pain. The abdomen was greatly distended, peristalsis was audible, no masses were felt.

Operation Median incision

Blood tinged fluid was found on opening the peritoneum. A large distended cecum "the size of a musk melon" was discovered in the epigastric region. This was delivered through the wound and found to be twisted one half turn on itself. The cecal mesentery was long. The peritoneal coat of the cecum was found to be split in several places. A cecostomy was performed using a Mixer tube. The wound was drained.

Course The patient recovered but required a secondary operation to close the cecostomy. A note dated 1915, four years after operation, states that the patient was alive and well and had not had a recurrence.

CASE 5 Female, aged seventy-one years, white

Admitted in 1913

Present Illness The patient had not had a bowel movement for seven days preceding entry but had experienced severe colicky pain at intervals. She vomited all day the day before admission. Enemas failed to produce results.

Physical Examination The patient was emaciated. The abdomen was tensely distended and tympanitic. A large mass was felt in the right side. Visible coils of intestine were evident.

Operation Local and "Anesthol" Left rectus incision.

A much distended and dilated cecum was found. The entire cecum and ascending colon were freely movable on a long mesentery. There was a complete turn upon itself of the ascending colon near the hepatic flexure. On the internal surface of the cecum was an area of gangrene. This area was incised, the cecum was untwisted and a cecostomy was done with a Mixer tube. The cecum contained half a basinful of liquid contents and much gas.

Course She was discharged on the seventeenth day with the cecostomy closed. One year later the patient was reported to have died suddenly apparently of other causes.

CASE 6 Female white unmorried, feeble-minded

Present Illness The patient ate heavily at a party the day preceding entry. At night she was nauseated and vomited. Next day she became much distended and began to have generalized abdominal pain. Enemas were given without result.

Physical Examination The abdomen was enormously distended more so in the right lower quadrant than elsewhere. A large mass was felt in the right lower quadrant.

Operation The cecum and ascending colon were enormously distended occupying the entire right half of the abdomen. It was found to be twisted one complete turn at the hepatic flexure and was black and gangrenous. There was cloudy malodorous fluid in the abdomen. The cecum was untwisted and then excised. The open ends of the colon and ileum were brought out through the wound and a tube fastened in each.

Course The patient died at the end of twenty-four hours.

Autopsy Streptococcus and B. Coll were cultivated from the blood. There was a terminal bronchopneumonia. Examination of the cecum and ascending colon showed gangrene and infarction.

CASE 7 W B C. B M 1358 October 4-28 1930

A married salesman aged forty-seven years.

Present Illness Two days before entry the illness began with colicky pain in the lower abdomen. It became quite severe and was accompanied by nausea. He slept little that night. The day before entry he vomited. The pain continued until admission to the hospital. Enemas produced a little gas and some fecal result.

Past History Twelve years ago he had a strangulated left inguinal hernia, operated upon which recurred five months ago. At that time he was operated on for what he thought was diverticulosis of the colon and had the hernia repaired again. At this time he is said to have had a cecostomy done. Since then he had had four attacks similar to the present one which subsided after a few days. He has always had some degree of indigestion and gas in the intestines.

Physical Examination The patient was a fairly well-developed and poorly nourished man of middle age. On admission he was sick-looking and drowsy. His temperature was 98 F., pulse 96. This later rose to 110. Respirations were 20. The blood pressure was 160/100. **Abdomen** There were lower

midline and left groin incisions of previous operations. The abdomen was immensely distended, more on the right than on the left. Peristalsis was visible and audible.

Preoperative Diagnosis Acute intestinal obstruction.

Postoperative Diagnosis Acute intestinal obstruction and volvulus of the cecum.

Operation Spinal anesthesia.

The abdomen was opened through the previous operative scar medial to the left rectus muscle. On opening the peritoneum a large very much distended portion of the large intestine presented. This was found to be the cecum which because of an anatomical anomaly was not attached to the posterior abdominal wall and was fully one foot in length. It was tremendously dilated with a diameter of at least six inches. It was found to be completely rotated with a point of kink in the ascending colon well above the ileocecal valve. This volvulus had carried the terminal ileum around underneath and at about twelve inches from the ileocecal valve the ileum was adherent. A two-inch segment of the ileum at this point was very badly damaged and dark purplish in color. When the volvulus was reduced the contents of the cecum emptied into the ascending colon. A small right rectus incision was made and a cecostomy done at this point using a large rubber tube. The median incision was then closed without doing anything to the damaged ileum as it was judged to be viable.

Postoperative Course The patient withstood the operation well and recovery was uncomplicated. During the first 24 hours the drainage from the cecostomy tube was 74 ounces the day following it was 36 ounces from then on it gradually decreased in amount to about 15 ounces in 24 hours. He remained in the hospital three weeks at the end of which time his wounds were well healed save for a small granulating area in the cecostomy wound. His bowels were moving normally. There was no fecal drainage from the cecostomy wound.

Subsequent Course The patient has been seen on an average of twice a year since operation. He has not had any attacks of abdominal pain but has rumbling of gas in the abdomen after eating certain foods or after eating a large meal. His bowels move regularly. He states that in general his abdomen feels more comfortable than it ever has before.

DISCUSSION

Anatomical Considerations All modern writers on the subject have emphasized the fact that volvulus of the cecum occurs only in cases where there is a congenital lack of fixation of the organ including in many cases the ascending colon. A long mesentery is often found but in many cases the cecum itself is almost devoid of any attachment.

Certain statistical studies have been made of the occurrence of a long mesentery and unattached cecum. V. Thun for example found 19 per cent of cases out of 388 cadavers where the cecal mesentery was long enough to allow the occurrence of volvulus. Waudel reported the same condition in 10 per cent of 600 cadavers.

The twist in the bowel always occurs at a point of fixation below which the bowel is unattached. This is often at the hepatic flexure but may be at any level in the ascending colon.

Occasionally the terminal ileum is adherent posteriorly and serves as a fixed point below which the cecum rotates. In one of the Massachusetts General Hospital cases (Case 2) the volvulus occurred at the point of attachment of a tumor, said to be a fibroma of the colon. Below this the bowel had rotated. In the majority of instances where the direction of rotation was stated it has been described as clockwise. This was true in the author's case, but no mention of the direction of the twist was found in the remaining six Massachusetts General Hospital cases. One exception to this assertion is a case reported by Littlewood in 1899, who found a counter-clockwise rotation of the cecum. Furthermore, Jacobsen says in his series of 20 cases the direction of the twist was equally right or left, and DuRoux also says that both types of rotation are to be found. The degree of rotation is of importance. It is apparent that a complete half-turn (or 180 degrees rotation) must take place before complete obstruction can result. Many cases, however, manifest a greater degree of rotation than this and one often finds it described as a "complete turn" or even more, as occurred in Case 2 of this series, where there were two and one-half turns. Obviously in such extreme degrees of torsion the arterial supply to the twisted bowel is usually much diminished or often completely shut off, as a result of which necrosis and gangrene inevitably follow. It is in the latter group of patients that mortality is most likely to occur and, as will be seen, especially in case an excision or resection of the cecum has been performed. Table I gives a summary of the anatomical data available in the present series.

Inciting Causes Although the primary cause of volvulus of the cecum is the absence of fixa-

tion of this organ, there are often other causes which induce the acute attacks. Overeating is generally admitted to be an inciting cause as perhaps occurred in Case 6 of this series. Many European writers have stressed this point. At any rate, distention of the cecum with feces or gas may cause it to flop over below some point of abnormal fixation, thus starting a volvulus. Once the blood supply begins to be shut off, the bacterial activity may increase and lead to further distention and increase of obstruction as pointed out by Homans. The importance of overindulgence in food is said to be enhanced when followed by vigorous exercise as pointed out by Pratt and Fallis and others. It is conceivable that with the cecum overdistended a sudden exertion or twist of the body might induce a volvulus. Ohman believed that volvulus of the cecum occurs more frequently among people who subsist on a coarse diet with a high roughage content such as is consumed by some of the European peasant classes. DuRoux was of the same opinion and states that this form of volvulus is very common in Russia, Finland, Poland, and Scandinavia where a coarse vegetable dietary is widely used.

Another occasional inciting cause appears to be the vigorous peristalsis which results from the use of certain drastic purgatives as Corner and Sargent emphasize. Further inciting causes mentioned by Jacobsen are the pressure of an enlarging pregnant or parturient uterus, violent coughing, diarrhea from any cause, and incarceration of a dilated cecum in a hernia, especially the umbilical type.

Diagnosis A diagnosis of acute volvulus of the cecum has rarely been made before operation. The clinical manifestations are those of intestinal obstruction without any further char-

TABLE I

Case No	1	2	3	4	5	6	7

Definite gangrene	+	0	?	?	Small area	+	0

acteristic signs except, perhaps, localized abdominal distention in the right half of the abdomen or the presence of a large tympanitic mass in this region which might suggest a distended cecum.

Treatment Immediate operation is obviously indicated in these cases. Temporizing with enemata and symptomatic treatment are now inexcusable relics of the past. Although the need for operation is always urgent, if one finds an elevation of the white count indicating as it does in all cases of strangulation of the bowel

evitably results from the cecostomy and which tends to prevent a recurrence of the volvulus. The mortality of this operation is low, 17 per cent in Jacobsen's series as compared with 50 per cent for the operation of resection. No doubt by earlier diagnosis and early operation this could be materially reduced. It has been found by many surgeons who have reported on their end results that no further cecopexy is necessary. A summary of the types of operation performed and the results obtained in this series is given in the following table.

TABLE II

Case No.	1	2	3	4	5	6	7
Excision—ends of bowel brought out	+					+	
Detorsion and cecostomy		+		+	+		+
Cecostomy alone			+

Recurred	—	—		0 in 4 yrs	0 in year she lived	—	0 3 yrs

damage to its blood supply, the necessity for immediate operation is manifest in order to prevent inevitable development of gangrene of the bowel.

The choice of operative procedure of course, depends upon the extent of damage to the cecum and the experience and skill of the operator. Extirpation of the cecum for gangrene has been followed by a high mortality. Of the seven cases presented above, two were subjected to excision leaving the cut ends of the bowel in the wound, and both died. Jacobsen states that the mortality of resection in these cases is 50 per cent or more. There is no doubt that the relative number of cases demanding excision because of severe damage to the blood supply and resulting gangrene is small. In general the simplest procedure which will relieve the obstruction, reduce the tension in the damaged cecum, release the compression of the blood supply, and if possible tend to prevent a recurrence of the condition should obviously be chosen. These indications are best met by the operation of detorsion of the cecum followed by a cecostomy. After having determined the direction of rotation, it is simple enough to untwist the bowel, thus releasing the compressed mesenteric vessels and partially emptying the cecum into the remainder of the colon. If one then performs a cecostomy, the contents of the damaged bowel can be thoroughly evacuated and the recurrence of distention prevented while it is healing. What is very important also is the fixation of the cecum to the anterior abdominal wall, which in

Both cases where the cecum was excised died (operative mortality of 100 per cent). One of the four cases where detorsion and cecostomy were performed ended fatally (a mortality of 25 per cent). Satisfactory follow-up reports are available in four of the seven cases and in all of these there was no recurrence. The last remaining patient of the group (Case 7) reports that he is in better health than ever before. So far as immediate recovery and subsequent course are concerned, the best results, therefore, resulted from detorsion and cecostomy, which has been the experience of all who have reported on this condition.

CHRONIC RECURRING VOLVULUS OF THE CECUM WITH SUBACUTE OBSTRUCTION

Undoubtedly many patients with a cecum mobile suffer from recurring transitory attacks of partial volvulus producing pain in the side and perhaps accompanied by vomiting. Spontaneous correction of the volvulus quickly terminates the attack. That this is true is suggested by the history given by many patients of acute attacks over a period of many years preceding a severe acute volvulus with persistent obstruction requiring emergency operation. Corner and Sargent conclude from a study of fifty-seven cases from the literature that there are acute subacute, and chronic types of volvulus of the cecum. That recurring chronic or subacute volvulus may occur is demonstrated by the following case report.

E. W., student nurse No. 203726 aged nineteen
Chief Complaint Intermittent right lower quadrant pain with nausea.

Present Illness Three months previously the patient was operated upon by Dr Arthur W Allen for acute appendicitis. At that time it was noticed that she had a long mobile unattached cecum. In the presence of an inflamed appendix it was not plicated and a simple appendectomy was done. Her recovery was complicated by an unusual amount of gaseous distention during the first few days. Soon after she began to get about, she had attacks of cramplike pain in the right lower quadrant which at first were not very frequent and for several weeks occurred only while she was in the upright posture, never while lying down. She returned to duty after a month of rest at home, but continued to have the attacks of pain and nausea even after attempts to control her constipation with diet and laxatives. (Her bowels had been constipated since operation.) The pain became more severe and finally the attacks began to occur even at night while in bed. Defecation failed to relieve them. They lasted usually a few hours and in the interval she remained free from pain.

Physical Examination Nothing abnormal could be determined by palpation and inspection of the abdomen. The appendix scar was well healed, flexible, and non tender.

X-ray A barium enema was reported as follows: "Barium passed without difficulty to the cecum. The colon was rather low in position. On the inner border of the cecum just above the entrance of the ileum there was a rather deep indentation. On defecation the lower part of the cecum emptied normally. The changes are slight, but are somewhat suggestive of an adhesive band across the inner portion of the cecum."

The case was discussed with Dr Allen who because he was about to start on a journey, requested the author to do the second operation.

Operation *Preoperative Diagnosis* Partial obstruction of the cecum from adhesive band.

Postoperative Diagnosis Intermittent volvulus of the cecum, cecum mobile, congenital anomaly of the ileum.

The abdomen was opened through a right paramedian incision close to the previous scar. Several filmy adhesions of the omentum to the old scar were found. The cecum was found to be freely movable, without attachment to the posterior abdominal wall. There were no adhesions to the point where the appendix had been removed. The cecum was found to be rotated one half turn to the left in a clockwise direction and the terminal ileum appeared to be coming off of the right side instead of the left. The last six inches of terminal ileum was firmly adherent at the point where the cecum should be. At about the middle of the ascending colon the cecum had flopped over the right colic artery which was short and tense enough to produce a shelf on the posterior abdominal wall. The ileum was freed up and the cecum was plicated and sutured to the denuded area left after freeing up the adherent ileum. In doing this the rotation of the cecum was corrected and when the abdomen was left the ileum lay in its normal relation to the cecum. By plication the cecum had been shortened to about its normal length. The adhesions of the ileum appeared to be congenital in origin.

Course The convalescence was uneventful except for the development of tetany. This was thought to be the result of a low vitamin diet for several weeks preceding operation, and alkalosis resulting from hyperventilation of the lungs produced by discomfort from the operation (overbreathing).

Subsequent Course The patient has been seen at frequent intervals since operation and has always been perfectly well. She has not had any recur-

rence of her former attacks. Her bowels move regularly.

The following is a diagram made shortly after operation in an attempt to illustrate the condition found.

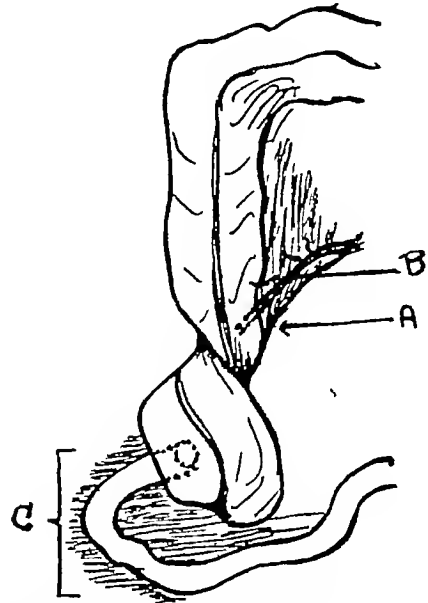

FIGURE 1 Diagram to illustrate torsion of cecum in case of chronic volvulus of the cecum.

A—fixed point.
B—right colic artery
C—area of fixation of ileum

In this case one sees an example of the influence of fixation of the terminal ileum in the right iliac fossa in facilitating volvulus of the cecum by acting as a fixed point. The importance of this condition is stressed by Corner and Sargent in their article on volvulus of the cecum where they state that a shortened fixed mesentery of the terminal ileum is the commonest cause of cecal volvulus in patients with a mobile unattached cecum. There was also in this patient a fixed point at the termination of the right colic artery which acted as a hinge upon which the cecum could turn. Correction of the abnormality of the ileum and fixation of the cecum sufficed to prevent a recurrence of the volvulus in this case.

*SUMMARY AND CONCLUSIONS

(1) Two types of clinical picture may result from volvulus of the cecum. The acute type with acute intestinal obstruction is that which is best known because of the obvious necessity for operation in such cases. The chronic or subacute recurring type is little known and undoubtedly rarely recognized. Seven cases of the former type and one of the latter type are reported here.

(2) There is always a congenital lack of fixation of the cecum with a point of attachment below which the bowel rotates. The variations of the factors and the effects of various precipitating causes at work have been discussed.

(3) The diagnosis is rarely made before op-

*I have been called upon recently to perform a resection of the 'pre-sacral nerve' for the relief of severe dysmenorrhea in this patient (E W No 303726). At this operation the cecum was found to be of normal size and still well fixed in its proper position.

eration. In the acute type the clinical picture is that of acute intestinal obstruction. The one characteristic suggestive sign is right-sided localized distention. In the chronic recurring type the history may suggest the diagnosis and the x ray may lend aid.

(4) Treatment in the acute type is immediate surgery directed toward relief of the obstruction, correction of the volvulus, and if possible prevention of a recurrence. These indications are best met by the operation of detorsion of the cecum followed by a cecostomy.

(5) Treatment in the chronic recurring type is directed toward correction of deformity and prevention of recurrence. This of necessity varies depending upon the conditions found but some method of cecal fixation must be employed.

(6) The results of surgery are good excepting when resection or excision is practiced in the acute cases, when the probable mortality is in the neighborhood of 50 per cent.

years ago by Barnard³. Drawings which are close reproductions of Barnard's diagrams are shown in figures 2, 3 and 4. In figure 2, the vari-

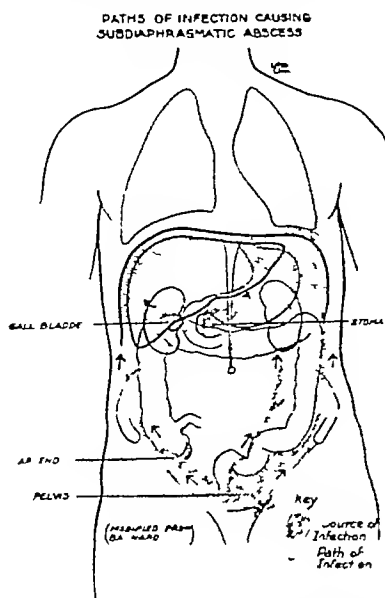

FIG 2 Diagram (after Barnard) which illustrates site of origin of intraabdominal infection and the pathways of spread. These points of origin are in the gall bladder in the duodenum in the pylorus in the appendiceal region and at times spread toward the right from the pelvic area. Note that the upward pathway on the right is shorter and more direct than on the left.

ous sources of intraperitoneal infection are given and the direction of the spread which the infection takes to reach the space beneath the diaphragm are shown. Figure 3 represents a sagit-

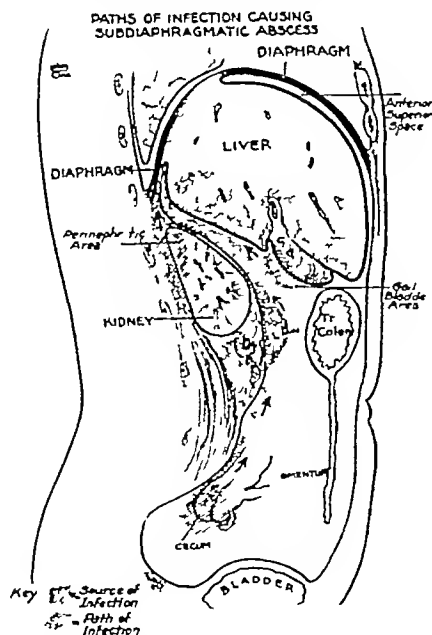

FIG 3 Diagram of sagittal view of right abdomen (just lateral to ascending colon) showing pathway of spread up the right gutter. Note close proximity of the perinephritic area to the posterior subdiaphragmatic space.

tal view of the right abdomen showing the path of travel up the right gutter (lateral to the cecum and ascending colon) to both the posterior and to the anterior space. This drawing

also illustrates the close proximity of the perirenal tissue to the posterior space. By direct extension, the infection has only to break through the parietal peritoneum at one point to involve the space beneath the diaphragm. The reflections of the peritoneum between the liver and diaphragm are shown in figure 4. This illus-

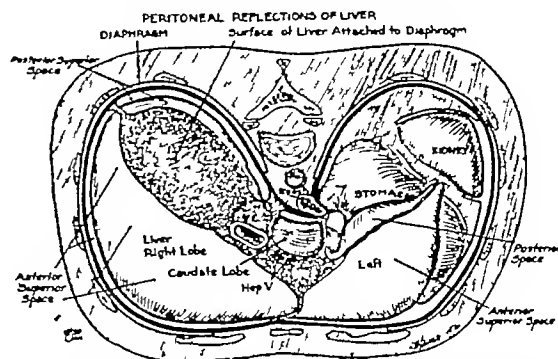

FIG 4 Diagram of superior surface of the liver showing line of reflection of peritoneum to form the diaphragmatic attachments of the liver. Note that this surface of the liver is divided into four spaces.

tration represents a view of the superior surface of the liver. The diaphragm has been removed. The shaded portion of the superior surface of the liver indicates the area of attachment of the triangular ligaments on each side and the falciform ligament anteriorly. The peritoneal reflections divide, therefore, the free spaces beneath the diaphragm into four compartments. It can readily be seen that the largest free portion of subphrenic space is over the right anterior and lateral aspects of the liver. The attachment of the right triangular ligament is broad, and extends posteriorly a considerable distance. The division of the two spaces on the right side has little practical significance because most collections are not limited strictly to either space but spread laterally over the free liver surface. All such collections are usually drained through a lateral incision either transpleurally or subpleurally.

That infection gains entrance to the spaces beneath the diaphragm most often by direct extension along the pathways mentioned cannot be questioned. It is maintained by some, however, that an infection of these spaces may be blood borne or result from a lymphatic spread. Such a method of travel is probably rare. Direct extension downwards from a pleural empyema may occur but even this is unusual. There was one such case in our series. The reverse is a much more common occurrence. A continuation of a subphrenic abscess into the chest was found in two of our cases. From a practical point of view, it can be concluded that ninety per cent of all subdiaphragmatic collections involve the right subphrenic space and result from a direct spread of infectious material from some other region in the peritoneal cavity. Factors other than the peritoneal reflections, also

influence the spread of intraperitoneal infections.

INFLUENCE OF RIBS AND DIAPHRAGM

The part that the pressure changes in the upper abdomen play has not been emphasized in proportion to their importance from an etiological standpoint. The thoracic cage covers the upper third of the abdominal cavity and together with the diaphragm fairly well surrounds the space we are discussing. The constant motion of the boundaries of this space incident to the act of breathing obviously creates variations in the intraperitoneal pressure of this portion of the abdomen. It is the general belief that the pressure in the peritoneal cavity is positive. It has been conclusively shown by one of us Overholt¹¹, and by others¹ that the intraperitoneal pressure in the upper abdomen is less than atmospheric pressure during quiet respiration. Overholt demonstrated in animals that the pressure in the upper abdomen oscillates in the negative phase corresponding to the changes in intrapleural pressure. In other words, it was shown, that during inspiration the pressure beneath the diaphragm was less (a greater negative pressure) than during expiration. This fact was explained on the following basis. During inspiration the outward movement of the ribs enlarges the space in the upper abdomen more than it is decreased by the descent of the diaphragm. The alterations that take place in the intrapleural and in the intraperitoneal pressure during the two phases of respiration are diagrammatically represented in figure 5. With

respiration the outward movement of the thoracic cage, which extends over the upper abdomen, increases the negative pressure during inspiration. Should a tube be inserted into the subdiaphragmatic space as is shown in this figure and its distal end placed under water a negative pressure during quiet breathing can be demonstrated. Water will rise in the tube to the highest level during inspiration. In two patients convalescing from a subphrenic abscess the drainage tube (with the wound itself packed with gauze) was placed under water as shown in figure 5. During inspiration fluid was sucked up in the tube and during expiration the water in the tube dropped. This observation demonstrates what may happen to free pus in the peritoneal cavity once it reaches the upper abdomen. The infectious material is actually sucked up to that part of the peritoneal cavity where the negative pressure is the greatest. The constant sucking effect of rib movements and diaphragmatic action is undoubtedly an important etiological factor in the formation of subphrenic abscess.

Fortunately, there are forces acting to prevent the upward spread of infectious material in the peritoneal cavity namely walling off of the process with granulation tissue, and the effect of gravity. The half sitting position of the patient so often employed postoperatively, is a valuable prophylactic measure. It is desirable that respiratory movements be kept as quiet as possible. Jerky or deep thoracic movements undoubtedly tend to increase the spread of an intraperitoneal infection.

DIAGNOSIS

The possibility of a subphrenic abscess confronts us whenever the general evidences of sepsis disturb the postoperative course of an abdominal case. After ruling out the common complications such as wound infection, pulmonary difficulties, pyelitis, or peritonitis, an abscess under the diaphragm must be considered. In figure 6 are shown representative temperature charts of patients who were proved to have subphrenic abscesses. All are suggestive of the accumulation of purulent material somewhere. Symptoms which may suggest such a location for an abscess are as follows:

- 1 Upper abdominal discomfort with or without pain
- 2 Difficulty in breathing
- 3 Referred pain to the chest, shoulder or neck
- 4 Hiccough.

Local signs which may or may not be present

1. Limitation of respiratory movements
2. Edema of the skin overlying the region involved
3. Tenderness and painful fist percussion
4. Downward displacement of the liver

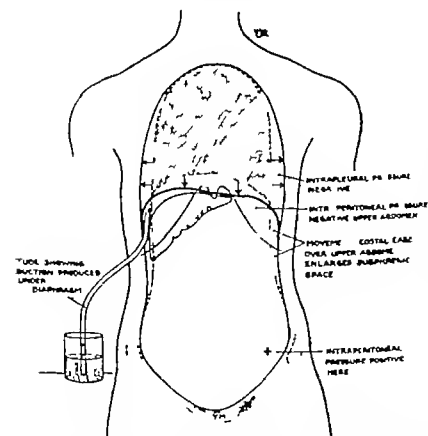

FIG. 5. Diagram which illustrates pressure changes to pleural and in upper abdominal cavities as a result of respiratory movements. The costal cage extends well down over the upper abdomen and therefore at the time of the outward excursion a suction is created in the subphrenic space. To illustrate this, a tube is shown draining the subphrenic area. Its distal end has been placed under water. During inspiration water is sucked up in the tube.

- 5 Palpable mass below the costal arch if the collection is large
- 6 Chest findings
 - a Elevated and limited motion of the diaphragm
 - b Decreased or absent breath sounds in the lower chest
 - c Physical signs of fluid in the chest above the diaphragm

phrenic lesion The diaphragm may be high, the lung clouded and a fluid level present Upon exploration of the subphrenic area a generalized involvement is found. The clinical course and abdominal signs should differentiate a local and a general infection within the peritoneal cavity 2 Liver abscess Single or multiple abscesses within the liver may be confusing

REPRESENTATIVE TEMPERATURE CHARTS

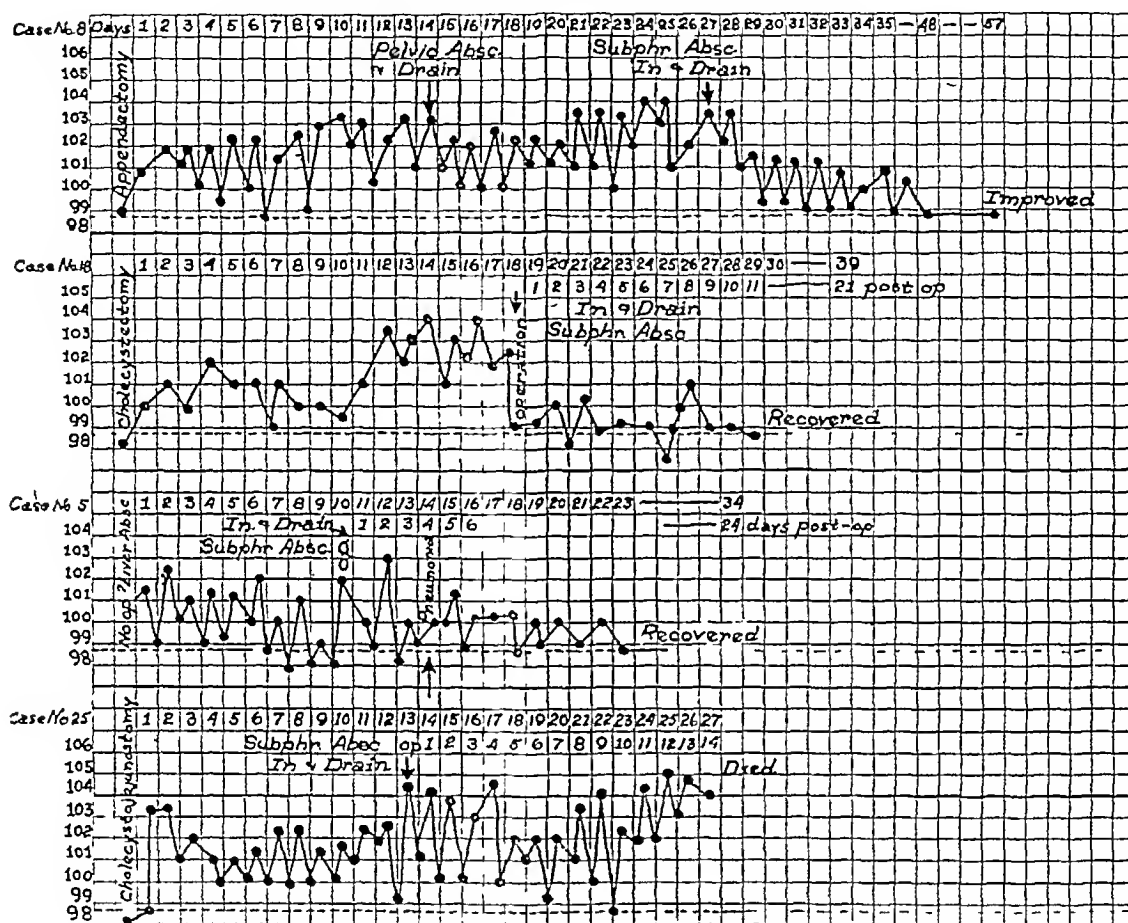

FIG 6 Reproductions of typical temperature charts in subphrenic abscess. Note that in some cases the temperature is sustained after the original operation. In others the curve has returned to normal then a recurrence of the elevated temperature occurred and was maintained until the subphrenic collection was drained.

- 7 X ray findings
 - a Elevated and fixed diaphragm
 - b Varying degrees of haziness of diaphragmatic shadow
 - c Costophrenic angle obscured
 - d Haziness of the lung field
 - e Displacement of the heart away from the involved side
 - f Gas bubble with fluid level under the diaphragm
- 8 Diagnostic needle aspiration

DIFFERENTIAL DIAGNOSIS

Other conditions leading to an erroneous diagnosis of subdiaphragmatic abscess may be listed as follows 1 The presence of a generalized peritonitis with apparent localizing signs has been, in our experience, one of the most difficult situations to separate from a true sub-

The clinical course is severe Jaundice may be present and a more definitely palpable liver edge would be expected The diaphragm is not so markedly elevated and the lung reaction is less pronounced X-rays fail to show a gas bubble between the liver and the diaphragm 3 Perinephritic abscess Edema and tenderness in the costovertebral angle are similar in the two conditions, but there is less change in the position of the diaphragm and less pleural reaction 4 Thoracic empyema, especially the encysted diaphragmatic type, may be confusing The lung base and diaphragm are obscured in the x-ray picture The history and clinical course are dissimilar An absolute differentiation can be made by needle aspiration, air injection, and x-ray reexamination 5 Postoperative uni-

lateral lower lobe or massive collapse. The diaphragmatic shadow in the x ray is elevated in both conditions and the lung base obscured. In lower lobe collapse, the heart is drawn toward the affected side while with a subphrenic collection it is displaced away from the side of the lesion. A fluid level below the diaphragm may outline the diaphragm and establish the diagnosis. Muller, Overholt, and Pendergrass¹² found a high diaphragm with some cloudiness of the lung base in the majority of patients after abdominal operations. Normally all postoperative patients who have had the abdomen opened within ten days show: 1. Elevation of the diaphragm. 2. Fixation of diaphragm. 3. Varying degrees of atelectasis of the lower lobes. 4. Air accumulations beneath the diaphragm. Since these x ray appearances are the usual and normal postoperative findings in all cases which have had a laparotomy, the problem of the differential diagnosis of subdiaphragmatic collections becomes more complicated. In figure 7 is

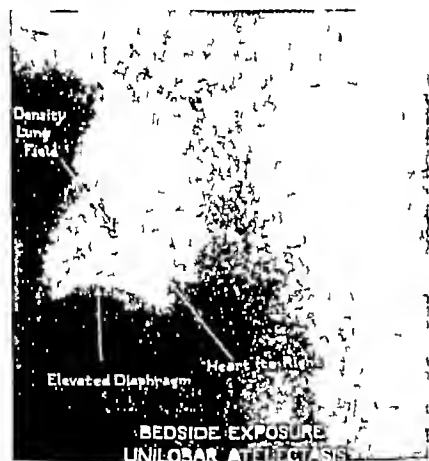

FIG. 7. Bedside roentgenogram of the chest of a patient who had a unilobar atelectasis on the right side which was proved two days later by autopsy. Note similarity of the appearance in this film and of that seen in the subphrenic patient. (Figure 8.) There is an elevated diaphragm, density of the lung fields, but the heart is displaced slightly to the affected side.

shown a postoperative bedside roentgenogram of a patient who had had a massive unilobar atelectasis proved at autopsy. The appearance is not unlike that seen in figure 8 which is shown to illustrate the so-called typical x ray features of subdiaphragmatic abscess.

TREATMENT

The basis of the treatment of subphrenic abscess is incision and drainage. Obviously this should be provided as soon as possible after the diagnosis has been established. Because of the

location of the abscess, the dangers of delay are great. In addition to the effects of prolonged sepsis an extension in any direction may contribute to a fatal outcome. The two-stage transpleural operation has been the one most universally employed. The first stage consists in the resection of segments of one or two ribs (8th or 9th) in the midaxillary line, under local anesthesia. The corresponding intercostal vessels, nerves, and muscle bundles are removed. This is an important step in the technique of the first operation. A removal of a segment of the intercostal vessels prevents hemorrhage at the time of the cauterization later. The removal of the intercostal nerve in the drainage area elim-

FIG. 8. Bedside roentgenogram of the chest of a patient who had a subphrenic abscess. Note the elevated diaphragm, the obscured costophrenic angle, the haziness of the overlying lung and the displacement of the heart away from the side of the involvement. Note also that the fluid level below the diaphragm is not apparent.

inates much of the pain. The parietal pleura is then anchored to the diaphragm with interrupted sutures around the circumference of the base of the wound. Gauze packing is then inserted and the wound is loosely closed over the gauze. The second stage is carried out twenty-four to forty-eight hours later which gives sufficient time for the drainage tract to be sealed. The wound is then re-opened, the gauze pack removed and the adherent pleura and diaphragm opened with the canter. An incision sufficiently large to admit the examining finger is made. The ramifications of the abscess cavity are explored and its trabeculations are broken down. Wide drainage is established and maintained by the use of cigarette drains and a tube for irrigation purposes.

The subphrenic space can in some cases be approached safely by an incision below the line of the pleural reflection (i.e., the costophrenic sinus) and the abscess cavity entered immedi-

ately without the necessity of a division of the operation into stages. This route of drainage can be established by placing the incision below the costal border and carefully sliding the exploring finger upwards under the ribs, extraperitoneally, to the abscess cavity. Ochsner favors an excision of a portion of the twelfth rib and thereby approaches the abscess retroperitoneally. He was able to show a lower mortality by this method than by any other. The operation advocated by Ochsner has two distinct advantages. The operation is a one-stage procedure and the dangers of a contamination of the pleural or peritoneal cavities during the process of establishing the drainage tract are lessened.

In managing the care of these patients after operation, it has been our practice not to disturb the original pack for four or five days. When the cigarette drains are removed, a continuous drip of half strength Dakin's solution is introduced and constant gentle suction applied to the outlet tube. The obliteration of the cavity is often prolonged if such suction is not employed.

SUMMARY OF CASES

In the past fourteen years there are in the Lahey Clinic records of twenty-five proved cases of subphrenic abscess. A summary of these cases is shown in table I. It is interesting to note that in the postoperative group the signs of a complicating peritoneal infection appeared within the first four to eleven days. The fact that localization with signs sufficient to make a diagnosis of a subphrenic abscess is often prolonged even after the appearance of the first complicating signs is borne out by study of the average length of time required to establish the diagnosis. Undoubtedly the presence of associated disease, such as general peritonitis, pneumonia, and lung abscess, as occurred in this series of cases, was responsible for the long interval between the first complicating signs and institution of drainage of the subphrenic abscess. This interval averaged between seven and fourteen days.

The summary clearly demonstrates the value of the x-ray in the diagnosis of this condition. The various signs looked for in the x-ray film are grouped together in the chart. The diaphragm was found to be elevated in every instance excepting two when such an examination had been made. Haziness of the lung field was second in frequency and was present in sixteen cases. We were surprised to find the shadow of a gas bubble below the diaphragm in only two of the cases in the entire series. There was cardiac displacement in three of the cases. This finding is dependent, of course, upon the extent of the rise of the diaphragm and of the associated pleural effusion. It becomes evident

from a review of the x-ray appearances in these cases that a gas bubble with a fluid level should not be considered one of the cardinal signs of subphrenic abscess.

In the majority of our cases, a diagnostic tap was done. Pus was obtained in fourteen out of twenty-one aspirations. There were seven cases, or one-third of the total with proved subphrenic collections, which gave a negative tap. It is our feeling, therefore, that this procedure is of doubtful value. Obviously, if pus is found, the area must be drained. Also, if pus is not found, it does not prove its absence and in the presence of a clinical and x-ray diagnosis of a subphrenic abscess, operation is justified regardless of the tap. We may rightfully ask then what may be accomplished by such a procedure? This procedure is not without danger, as the pleura may be traversed by a contaminated needle. In one case in our series empyema complicated the treatment, due either to the tap or to the transpleural drainage. Fortunately this case survived. Fluid was demonstrated in the pleural cavity by x-ray or was found at the time of the first-stage transpleural operation in ten of our cases. The presence of fluid in the chest probably explains the frequency in the x-ray of haze or of an increased density of the lung field. In fact, it is quite likely that the x-ray appearance of the overlying lung is due to pleural fluid accumulation and not to an actual edema or inflammatory reaction in the parenchyma of the lung itself. Our experience in regard to the presence of pleural fluid, therefore, is contrary to that of Ochsner and Graves.⁷ We agree with Clute¹⁴ and Beyer⁶ who found that pleural effusion is one of the frequent and often is an early sign of the development of a subphrenic abscess.

RESULTS

Every patient who had a diagnosis of subphrenic abscess, no matter what other condition was present, has been included in this report. In reviewing the cases, it was found that eight deaths occurred. From an analysis of these cases, it was found that none died primarily of the subphrenic condition per se. One patient entered in a moribund condition and was not operated. Of the seven others all died of the primary condition which originally gave them their subphrenic abscess. In six of the seven cases, autopsy established this fact. For instance, in case twenty-three, a complete gastrectomy was done and a leak of the gastro-esophageal suture line occurred. The patient developed a left-sided subphrenic abscess, as well as a mediastinal infection and died of generalized sepsis. It is, therefore, difficult to appraise such a series of cases and determine to what extent the development of the subphrenic abscesses had to do with the deaths.

There can be little doubt, however, that the

presence of a collection of pus in such a loca-
tion contributed to the high mortality in this
group. If we are to be self-critical in regard to
the management of these patients, it might be
said that the period of time between the onset of
complicating signs and the institution of drain-
age was too long. All of the so-called cardinal
signs of such a collection need not be present to
warrant exploration of this space. Evidence of
sepsis following an abdominal operation with-
out discovery of a cause elsewhere together with
a unilateral elevation of the diaphragm with
varying degrees of haziness of the lung field
above should be enough. Exploration subpleu-
rally or transpleurally can be done under local
anesthesia with slight risk. The early and ade-
quate drainage of a subphrenic abscess will be
an important contributing factor in securing a
lower mortality rate in patients with subphre-
nic infections.

SUMMARY

- 1 Subphrenic abscess as a complication of abdominal disease has been discussed.
- 2 Etiological factors and pathways of spread have been considered.
- 3 Diagnostic procedures have been com-
mented on.

- 4 The influence of a negative pressure in the upper abdomen and of the sucking action of costal and diaphragmatic action upon the formation of collections in this area has been pointed out.
- 5 A brief report of experiences with twenty-five proved cases has been given.

THE USE OF SODIUM EVIPAL AS AN ANESTHETIC FOR SHORT SURGICAL PROCEDURES*

BY WALTER E. GARREY, M.D.,† AND ROY B. COHN, M.D.†

THE need for a readily available and less cumbersome anesthetic for short surgical procedures impelled us to try anesthesia with sodium evipal. It is a barbituric acid compound which has now been in use nearly three years as an intravenous anesthetic. It has seemed particularly adaptable to work in the out-patient dispensary and emergency room where it chiefly displaces gas-oxygen anesthesia.

EXPERIENCE ELSEWHERE

The reported clinical experience with this drug is large. There are an extensive number of case reports in the German literature which have been comprehensively summarized in English by Killian¹ of Freiburg. These total 15,000 cases with one death in a woman very ill with puerperal sepsis. Sebenius² of Frankfurt has reported in English his experience with 200 short surgical anesthetics with sodium evipal. Jarman and Abel have published three articles covering respectively their first hundred, first thousand³, and first two thousand⁴ cases and the

reader is referred to their articles for a scholarly and comprehensive presentation of the subject. They have extended its use in combination with other drugs to longer anesthesia.

DOSAGE AND ADMINISTRATION

The drug is dispensed in sterile glass ampoules containing one gram of the powder. For administration this is dissolved in ten cc of sterile distilled water.

A safe maximum dose may be calculated on weight basis by multiplying the patient's weight in pounds by 0.06 to obtain a safe maximum number of cubic centimeters of solution to inject. Thus an adult weighing one hundred and fifty pounds could safely receive a total of nine cc of solution containing 9 Gm of the drug.

We have preferred to use a fractional method of administration injecting three to four cc into the vein at the rate of one cc each fifteen seconds and stopping the administration there when the patient was asleep. We have then left the needle in the vein so that more might be injected if the patient showed any evidence of recovering before the operation was through. It is surprising how often the smaller doses of 2 to 4 Gm of the drug will induce loss of con-

From the Surgical Services of the Massachusetts General Hospital.

*Garrey, Walter E.—Resident, East Surgical Service Section, Massachusetts General Hospital. Cohn, Roy B.—House Officer, East Surgical Service, Massachusetts General Hospital. For records and addresses of authors see "This Week's Issue," page 322.

sciousness for long enough to do the required manipulation and the recovery period is thus shortened to a few moments. This method provides the maximum safety factor in allowing for individual susceptibility and for the fact that the effective dose is not the same for different individuals of the same weight.

The drug is a respiratory depressant. For this reason we have had available at all administrations a tank of oxygen with five per cent carbon dioxide. We have also had on the anesthesia tray coramine (5 cc) for intravenous use and an ampoule of adrenalin. We have not had any occasion to use these. In other clinics temporary but disturbing cessation of respiration has been noted in cases where a preoperative opiate has been given. Although opiates or scopolamine will lengthen the effect of the drug they are not necessary in the type of case most suited to evipal anesthesia. It has seemed to us dangerous to pyramid two known respiratory depressants.

PERSONAL EXPERIENCE

One or the other of us has personally administered the anesthesia in 120 cases and observed all the inductions, the maintenance and the majority of recoveries. The following types of cases presented themselves:

- 1 Out-Patient and Emergency Room Cases
 - Incision and drainage of abscesses and carbuncles
 - Incision and drainage of felons, paronychias, septic fingers
 - Extraction of multiple and abscessed teeth
 - Suture of lacerations (children and about face)
 - Reduction of Colles', Potts', nasal and greenstick fractures
 - Forearm fractures, dislocated shoulder and thumb
- 2 In-Patient Cases
 - Drainage of sepsis
 - Peripheral and intraabdominal abscesses
 - Tenosynovitis, etc
 - Neurosurgical
 - Alcohol injection, chiefly of Gasserian ganglion
 - Minor gynecological
 - Cauterization of cervix, dilatation and curettage
 - Uterosalpingograms Drainage of Bartholin's abscess, etc
 - Minor rectal
 - Drainage of perirectal abscesses
 - Excision of strangulated hemorrhoids
 - Excision of anal fistula
 - Painful proctoscopy

Some of the fractures and rectal cases could well have been done with local anesthesia, but it led to the patients greater physical and mental

comfort to be asleep. Sodium evipal anesthesia is not adapted to rectal cases requiring dilatation of the sphincter. It is adequate, however, for removal of external hemorrhoids or simple fistula. In pelvic cases the abdominal muscles may be unrelaxed and a good bimanual examination difficult. Many of the emergency room cases were children and the use of evipal was a very real comfort. The anesthesia was found ideal for the eighteen neurosurgical cases and the ten dental cases. All the patients have liked the anesthesia and many have been very enthusiastic about it, in comparison with previous experience with other anesthetic agents. Our youngest patient was an eight months infant weighing eighteen pounds, given sodium evipal for drainage of a septic tendon sheath of the finger. He had recently recovered from pneumonia and had not taken avertin well on a previous occasion. One tenth of a gram was injected into the external jugular vein for induction and with a total of 0.14 Gm the infant slept soundly for ten minutes of the operation. Our oldest patient was eighty years, and the eight patients of age sixty years or above did well.

(a) Induction and Maintenance. We have noted nothing at variance with other observers. Induction has been dramatically quiet. Between thirty seconds and two minutes after commencing injection the patient, often preceded only by a single yawn, will be in a deep sleep. The pulse remains the same, the blood pressure drops from ten to thirty millimeters systolic. The respirations have always been regular.

We have used minimal doses. The out-patient cases (adult) have received from 2 Gm upwards and have slept from four to ten minutes on these smaller doses. The length of sleep has not been constant but has been not less than eight and usually fifteen minutes for the maximum dose of about one gram.

We have observed the common slight muscular twitching in about one-third of the cases. About one-fifth of the patients have remained somewhat rigid and two very husky foreign men have had no muscular relaxation even with the larger dose.

(b) Recovery. This has been rapid in the minimal dose cases (3-4 Gm) which are often widely awake in from five to ten minutes. Those having larger amounts (8 to 10 Gm) may remain drowsy or mentally foggy for thirty to ninety minutes. If allowed up too soon they complain of vertigo and behave like intoxicated persons. No case has vomited. Several have mentioned nausea, but this has not been common or unpleasant. Two patients, both husky men, were obstreperous during recovery, one for five minutes and another for twenty minutes. None of the others were even unusually restless. The anesthesia was repeated on one of these and he reduplicated his previous obstreperous performance.

The out patient cases have been kept for recovery one or two hours and the rare doubtful case sent home in company with a competent friend or relative.

(c.) **Untoward Reactions** In two cases we observed cyanosis if the jaw was not held for ward and tongue prevented from sagging back. This is most important and, as advocated by Jarman and Abel a person other than the administrator should be at the head of the table to insure a clear airway. There were no other observed circulatory, respiratory, or other complications.

The blood pressure was accurately followed on fifteen patients and consistently fell from twenty to thirty per cent below preoperative level. In the remainder of cases the administrator kept his finger on the radial pulse which did not change perceptibly in quality or rate.

CONTRAINDICATIONS

In general we have felt that any anesthetic agent on trial should be used for good risk patients, so sodium evipal has not been used in the case of any very ill or debilitated patient. Because its chief potential danger is that of a respiratory depressant, we should hesitate to use it in anyone already cyanotic or in an asthmatic or decompensated cardiac patient. We have followed the conservative course in avoiding its use in patients with hypertension or severe liver

or renal disease. Allergic reaction is possible and we have seen urticaria and angioneurotic edema after ingestion of evipal by mouth.

CONCLUSION

1 Sodium evipal anesthesia seems especially adaptable to brief manipulations that would otherwise require a general anesthetic.

2 The chief advantages are the ease of administration, the rapidity of induction and recovery, the freedom from psychic trauma or unpleasant after-effects.

3 There is considerable variation in individual susceptibility to the drug. For this reason the fractional method of administration is the safest and most satisfactory.

4 Observations in 120 cases are briefly recorded.

5 Until more extended experience with the drug has been obtained its use should be confined to the "good risk" patient.

We are indebted to Dr. H. H. Bradshaw, chief of the anesthesia service of the Massachusetts General Hospital for guidance and advice.

CYCLOPROPANE, A NEW AND VALUABLE GAS ANESTHETIC*

BY L. F. SISE, M.D.,† P. D. WOODBRIDGE, M.D.,† AND U. H. EVERSOLE, M.D.†

THE recent introduction of cyclopropane to clinical use by Waters of the University of Wisconsin has given us a very valuable new anesthetic agent of most interesting properties.

HISTORY

It had been found that laboratory samples of propylene (C_3H_6) possessed excellent anesthetic properties without appreciable toxic action but when larger quantities were manufactured these were found to have a toxic action on the heart. Henderson and Lucas in hunting for the source of this toxic action investigated cyclopropane, an isomer of propylene which frequently appears in its preparation. To their surprise they found that cyclopropane was an excellent and very powerful anesthetic with low toxic action.^{1,2} Following this report Waters after some further laboratory investigation, started its clinical use on human be-

ings. The gas has been studied from different angles by various groups of investigators at the University of Wisconsin, and Montreal.

PHYSICAL PROPERTIES

Cyclopropane is a hydrocarbon gas with the empirical formula C_3H_6 and is therefore isomeric with propylene. Structurally it is a ring compound.

Its molecular weight is 42.05 and its density as compared with air is 1.46. Thus the undiluted gas tends to drop to the floor somewhat as does ether vapor, the density of which is 2.6, and does not float or so readily diffuse as does ethylene, the density of which is 0.975.

Its fat to water solubility is very high the ratio being given by Henderson and Lucas as 64 to 1 as compared with 13.2 to 1 for ethylene and 2.5 to 1 for ether. This characteristic ex-

plans the slowness with which complete saturation and stabilization is obtained

It is an inflammable gas, and is explosive when mixed with certain proportions of air or oxygen. As with other gases the exact limits of explosibility vary widely under different conditions. Thus in breathing bags containing a spark plug it could not be exploded in mixtures below 19 per cent⁷, but in a Hempel explosion pipette it could be exploded in mixtures down to 2½ per cent¹. Buckman and Wardell of the Ohio Chemical Company give the explosion limits of this gas as determined in the Hempel explosion pipette in per cent by volume as follows¹

	Lower Limit	Upper Limit
Cyclopropane and air	3 0	8 5
Cyclopropane and oxygen	2 5	50 0

The lower limits are about the same as for ethylene, but the upper limits are considerably less. The important point, however, is that ordinary anesthetic mixtures of cyclopropane (15 per cent) are well within the explosive limits while ordinary anesthetic mixtures of ethylene (80 per cent-85 per cent) are outside its explosive limits.

Care should of course always be exercised when using any inflammable anesthetic agent, but in using cyclopropane, where we know that the anesthetic mixture is not only inflammable but explosive as well, this precaution should be particularly searching and insistent.

The odor is characteristic and not disagreeable. The gas is slightly irritating. This irritation is so slight that in anesthetic dilution it is not noticeable. With the higher concentrations, however, above approximately 50 per cent, laryngospasm may be caused.

The gas liquefies at a lower pressure than does any other of our present anesthetic gases. The tank pressure is about seventy-five pounds as against about 800 pounds for nitrous oxid and 1,250 pounds for ethylene. Present product is said to be about 99½ per cent pure.

PHARMACOLOGY

Absorption of the gas by inhalation is quite rapid but saturation and equilibrium are not established with such rapidity as with nitrous oxid or ethylene. Even when a closed system is used the gas disappears from this system with considerable rapidity so that it is necessary to keep adding gas in order to maintain the same concentration in the system⁵. It seems probable that this disappearance of the gas is due to its absorption by the lipoids of the body, for which it has a high affinity. Waters and Schmidt found the concentration with human beings for third stage or surgical anesthesia to be in the first plane 7.4 per cent (but with very wide variation), in the second plane 13.1 per cent (less variation), and in the third plane 23.3

per cent. In this third plane the extreme variations were slight, being from 21.1 per cent to 27 per cent⁸.

Breathing is very quiet, and there is not the initial stage of stimulation seen with nitrous oxid, ethylene or ether. Thus gives the impression that respiration is depressed, yet there is no decrease in rate or minute volume until beginning intercostal paralysis. All observers agree that breathing ceases well before circulation.

Circulation is well maintained until the beginning of respiratory depression. At this time the blood pressure begins to drop. Cardiac irregularity does not usually appear until respiration is severely affected and about to cease. Seevers and Meek have made a study of this with the electrocardiogram in dogs⁶. They found the average concentration of the gas when irregularities appeared to be almost 50 per cent. They found the early irregularities to be nodal rhythm or ventricular extrasystole although partial or complete auriculoventricular block was not uncommon. Later effects consisted of ventricular tachycardia and auricular and ventricular fibrillation. That high concentrations of this gas may have a decidedly toxic action on the heart is shown by the death from circulatory failure of two dogs in this series in spite of the presence of adequate alveolar oxygen. Inflation with pure oxygen failed to effect recovery. The concentration of the gas was 52 per cent in one case and 71 per cent in the other, far above the range for third stage anesthesia.

The metabolic effects of cyclopropane are strikingly few. There is a slight rise in the blood sugar. The pH and the carbon dioxide combining power are affected but very little². There is no effect on liver function⁴.

CLINICAL USE

This gas is very expensive. The first lot which we used cost \$1.25 per gallon. The cost has since been gradually reduced to about forty cents per gallon. As ethylene and nitrous oxid cost in the vicinity of two cents per gallon, it can be seen that even this reduced price is still very high, by comparison. If it attains to popular use, however, a further considerable reduction in price will probably occur. This high cost of the gas precludes the employment of any method of use which wastes any of the gas. The carbon dioxide absorption technique described by one of us in this Journal⁹ is therefore the only present method adapted to its use. However, the power of the gas is such that it is unnecessary to waste any gas in a washing out process during induction such as is necessary with ethylene or nitrous oxid in order to get the highest possible concentration. These facts make it possible to produce and maintain anesthesia with amazingly small quantities. In the average adult, if the mask is tight fitting and the closed system does not leak, it is usually pos-

sible to produce third stage anesthesia of an hour's duration with approximately a gallon of the gas. In resistant cases two to three gallons may be necessary, and if a leak is present any amount may be used. In a number of cases less than half a gallon has been sufficient. This brings the expense within reasonable limits and well under the cost of gas anesthesia with the older agents and methods.

In selecting a gas machine it must be remembered that this gas is solvent for rubber and rubber compounds. As the seats of reducing valves are commonly made of a rubber compound, this prevents the use of these valves with cyclopropane until such time as a more resisting compound is used. The pin type of valve is therefore best adapted to the use of this gas. As the tank pressure is so much lower than with other gases, this type of valve is much more satisfactory here than it has been with the other gases.

This solvent action of the gas on rubber is not manifest in concentrations sufficiently low to be within the anesthetic range. Thus the ordinary rubber breathing bag, tubing and filter valves may be retained in the gas machine without essential damage.

The procedure at induction is quite different from that with other gases, where large quantities and high concentrations are commonly used. When first using cyclopropane those who are accustomed to the other gases are very apt to overdose the patient, sometimes with alarming results. The high power of the gas must be kept constantly in mind as must also the fact that there is a distinct lag in its effect, not noticeably present with the other gases.

Various methods may be used for induction. We have found the following general scheme satisfactory with minor changes to suit the individual case. A rapid flow of oxygen is started. When the amount in the breathing bag becomes enough to accommodate tidal breathing the mask is placed on the face and the oxygen flow is reduced to the estimated basal requirement, usually 200 to 300 cc. per minute. Cyclopropane is now started at 400-700 cc. per minute. This flow is maintained until, usually in about one to two minutes' time, there is loss of lid reflex. The flow is now either reduced to about a third of this amount for perhaps another minute, or is cut off entirely depending on the depth of anesthesia now desired. Thereafter the oxygen flow is regulated to the basal requirement of the patient, and perhaps small amounts of gas are admitted as indicated.

During maintenance we have had considerable difficulty in correctly estimating the depth of anesthesia. This estimation appears to us more difficult with this gas than with any other in halothane anesthesia with which we are familiar. In general the signs of depth are similar to those with ether anesthesia and are not difficult

to detect with deepening anesthesia provided the deepening is reasonably slow. In the third or surgical stage of anesthesia, activity of the extra-ocular muscles is maintained in the first plane, and ceases as the second plane is approached, while intercostal activity is maintained in the second plane and ceases as the third plane is approached. If the progress of the anesthesia has not been too rapid, the signs up to this point are not difficult to recognize, but when the desired depth of anesthesia has been obtained it is often most difficult to detect the occurrence of a lightening from this depth. Each of us has on more than one occasion had the embarrassing experience of failing, even with most careful scrutiny, to detect any change in breathing, in eye signs or other phenomena to indicate change in depth till the patient made some obvious sign of lightness like raising the knee!

Experience has of course been a help, for most of these occurrences have been in our early work. Preliminary medication is also quite important as it appears to cloud the signs of anesthesia. These signs are much clearer if little or no premedication has been used.

This undetected lightening of anesthesia may be to some extent guarded against by admitting at not too frequent intervals (five to ten minutes) small amounts (about 100 cc.) of the gas. While this is in one way a very unsatisfactory procedure, inasmuch as it does not clear up the signs of anesthesia, yet it is an entirely logical procedure, since we know that stabilization is very slow and that for a considerable period (over an hour) the gas is being lost from the closed system probably to the lipoids of the body. The above procedure replaces this gas which we know is being lost.

Those who begin the use of cyclopropane should bear constantly in mind its great power and its rapidity of action. The effects of the higher concentrations are simply astounding and are unbelievable to those who think in terms of the weaker gases nitrous oxide and ethylene. With these gases our chief warning comes from signs of anoxemia. With cyclopropane on the other hand drastic overdosage takes place in the presence of abundant oxygen. This is a most important point to remember. If too high concentrations of the gas are used the patient passes from one stage of anesthesia to another with such rapidity that the successive stages cannot be recognized and he, therefore, may plunge into extreme overdosage with great rapidity and abruptly cease breathing. Relaxation is such that breathing is easily obstructed. Crowing respiration is here common, and the obstruction may become extreme so rapidly as to constitute an acute emergency. Much preliminary narcotic medication is inadvisable since cyclopropane lacks stimulating properties to offset the narcotic effect. If much preliminary nar

cotic has been used, undue depression or abrupt cessation of breathing may result. The medication may be given with a view to preoperative apprehension only, since anesthesia is satisfactory with no premedication whatever. We, therefore, have discontinued the use of a barbiturate and use only morphine sulphate grains 1/8 and scopolamine hydrobromide grains 1/200 to 1/150.

The possibly deleterious action of this gas on the heart muscle should be kept in mind. Note that in the experimental work of Seevers et al. two dogs died of circulatory disturbance in the presence of adequate oxygen and in spite of artificial respiration. Hence the pulse should always be carefully watched, and the advent of any irregularity or any considerable change in rate in either direction should dictate a prompt lightening of the anesthesia.

RECOVERY

Recovery of consciousness is rapid, approximating that from the other gases, but complete desaturation does not take place for several hours. The estimation of postoperative results may be made most accurately from the very careful and painstaking study by Schmidt and Waters⁶, with which our clinical impressions are in accord. In this study 2,200 cases under cyclopropane were compared with a like number under ethylene, nitrous oxid or ether. Schmidt and Waters found: 1. There were fewer respiratory complications under cyclopropane. 2. There was more circulatory damage under cyclopropane. This statement they qualified, feeling that further study is needed. 3. Nausea and emesis were less in major surgery but possibly more in very short and minor operations.

USES

The combination of certain properties in cyclopropane make it unique among anesthetic agents. Probably no other agent combines in itself as does cyclopropane speed both in induction and recovery, high oxygen supply during anesthesia, and power to produce a considerable degree of relaxation, together with a minimum of deleterious effects on the various organs and functions of the body. The quiet type of breathing which it produces is also desirable. This combination of properties makes it a very valuable anesthetic agent.

On the other hand its very speed and power make it potent for danger unless these properties are thoroughly appreciated and allowed for, and the cardiac effects in high concentrations should always be borne in mind. The explosibility of anesthetic mixtures of this gas must also be remembered and carefully guarded against. It should, therefore, not be employed where diathermy or x-ray or other high potential electrical equipment is to be used.

Its chief fields of usefulness appear to be as follows:

1 *Chest surgery*. Here the high oxygen supply is a great advantage. These patients almost always have a lowered vital capacity. The position during operation and the release of negative pressure in the chest often put them at a great disadvantage in breathing. The power of the anesthetic is of value in overcoming the marked reflexes which often arise from stimulation of the pleura. The quiet breathing is a help to the surgeon in his work, and rapid recovery of cough reflex is valuable.

2 *Respiratory obstruction*. Here the high oxygen supply is also of value. Where practical we have always used intratracheal anesthesia in these cases. The power to relax the jaw and larynx makes cyclopropane one of the best agents for intubation.

3 *Marked anemias*. The advantage of the high oxygen supply is here obvious.

4 *Cardiac cases*. Here again the high oxygen supply appears advantageous, especially where decompensation is present. Because of its deleterious action on the heart muscle, however, its value here is subject to qualification. This deleterious action, however, has been definitely shown only in comparatively high concentrations. In the weaker anesthetic mixtures it has not been shown and clinically does not appear to be present. If, therefore, the contemplated operation demands considerable depth, cyclopropane might not be so advantageous as some other anesthetic. But in all other cases, where marked depth is not necessary, it is our clinical impression that the high oxygen supply, the quiet breathing, and the comparative lack of stimulation to the pulse and blood pressure more than compensate for the possibility of deleterious action. Further experience and study are necessary, however, before more definite statements can be made.

5 *States of marked debility and shock*. The advantages and qualifications are very similar here to those already discussed for cardiac cases.

6 *Short procedures where a moderate amount of relaxation is desirable*. This would include, for example, pelvic examinations, simple reduction of fractures (but not in x-ray room) and manipulation of joints.

7 *Possibly abdominal operations*. Our own experience in this field is too limited to hazard an opinion. From the experience of some others, however, it would seem probable that those surgeons who have been accustomed to operating under nitrous oxid or ethylene would find the increased relaxation of cyclopropane very gratifying, while those who are used to the relaxation of spinal anesthesia would not be so enthused.

8 *As an adjuvant to other anesthetics* With patients who are resistant to ethylene the addition of a comparatively small amount of cyclopropane to the mixture will almost always result quickly in the attainment of a satisfactory plane of anesthesia, and at the same time make possible an adequate supply of oxygen. The change wrought in these cases is most gratifying. It should be remembered, however that if more than a small amount of cyclopropane is added, a considerable amount of oxygen will also have to be added. The proportion which the oxygen will then hold to the two inflammable gases, ethylene and cyclopropane will probably be such as to place the resulting mixture well within the explosive range whereas an anesthetic mixture of oxygen and ethylene alone is usually entirely outside the explosive range. But, if the cyclopropane added is only just sufficient to produce the desired effect the oxygen supply may still probably be kept down sufficiently to keep the mixture outside the explosive range.

If instead of ethylene nitrous oxide is being used, the addition of more than a very small amount of cyclopropane even without increased oxygen supply will, because of the oxidizing

power of nitrous oxide, place the mixture within the explosive limits, just as is the case when ether is added to nitrous oxide mixtures.

Tables 1, 2, and 3 are compiled from a series of our cases taken in succession without selection. It includes cases of straight cyclopropane anesthesia only, not any cases in which other anesthetics were used in combination.

In these statistics the most noticeable fact is the large number of chest operations (124 out of 184 operations). This appears to us the field to which cyclopropane is most suited.

Of the seven deaths, it does not seem possible that cyclopropane was directly responsible in any case. It is conceivable that it may have been one of the factors involved in cases 4, 5 and 6. That any other anesthetic would have been better in these cases seems doubtful.

The number of cases showing mucus coughing, grunting, spasm and poor respiration does not seem remarkable in view of the large number of chest cases. The number recorded as showing obstruction and probably those in which depth of anesthesia was not correctly gauged seem less than actually occurred. Some cases doubtless were not recorded. The cases of cardiac irregularity are of interest but the number does

SUMMARY

Cyclopropane is a hydrocarbon anesthetic gas of great power, giving adequate anesthesia with concentrations in the vicinity of fifteen per cent Its power and rapidity of action are of potential danger if it is carelessly used In high concentrations it may have a deleterious action on the heart Anesthetic mixtures are within the explosive range The high percentages of oxygen which can be used with it make it of great value in chest surgery, respiratory obstruction, and some other conditions Because it apparently combines low toxicity with fairly powerful anesthetic action it could conceivably encroach on the fields of virtually all the other commonly used anesthetic agents

THE MANAGEMENT OF ROENTGEN SICKNESS*

BY GEORGE W. HOLMES, M.D.,† AND FRANCIS T. HUNTER, M.D.†

WITH the more generalized use of the Roentgen ray in the treatment of neoplastic diseases, particularly with the development of the massive dose technique, the prevention and treatment of so called "Roentgen sickness" have become of increasing importance In the past few years the subject has received considerable attention, many theories have been advanced to explain the phenomenon and an equal number of methods of treatment have been advocated With the exception of the suggestion made by Pfahler, in 1916, that unpleasant odors in the treatment room may play a part in causing the sickness, none of the various theories have been generally accepted

At the Massachusetts General Hospital, in the last few years, we have gradually developed a routine management which we believe has definitely decreased the amount of sickness and which offers some alleviation of symptoms when they do occur In our study of the problem it soon became apparent that there are, roughly, three types of sickness seen in patients undergoing Roentgen treatment First, there is that group of cases which we have termed "toxic sickness", which shows marked nausea and vomiting following heavy doses of x-ray therapy over large masses of tumor tissue and which, being extremely sensitive to irradiation, rapidly break down and are absorbed during the course of treatment This form of sickness is fairly well recognized and is, possibly, a toxemic phenomenon produced by the extra work thrown upon the liver in its effort to detoxify and

deaminate partially split proteins The obvious method of avoiding the symptoms of nausea and vomiting in such cases is to adjust the dosage to such a small amount that rapid breakdown of tissue does not occur The second group we have classified as "psychic sickness" and this phenomenon occurs in patients who have been previously made sick by exposure to some form of irradiation, or occasionally in high-strung, nervous individuals who have been told by well meaning friends or nurses that x-ray treatment always produces sickness Nausea or vomiting or both, usually occur in this group either while they are being treated or very shortly afterwards, and they belong to the group which complain of odors in the treatment room, of which Dr Pfahler has written The third group is by far the most important and may be called "true Roentgen sickness" The cause of this is not known with any certainty, but there is some evidence which points to temporary interference of liver function by heavy irradiation It is this group that we particularly wish to discuss

It is well known that the severity of the general reaction—that is, the proneness to develop anorexia, nausea or vomiting after irradiation—depends upon the size of the area and the part of the body treated, the amount of irradiation given at any one sitting, and the frequency with which the dose is repeated It is also generally accepted that treatment over the abdomen or thorax is more likely to produce sickness than irradiation over other parts of the body There appears to be some relation, too, between the severity of the reaction and the nearness of the treated area to the liver If one groups the symptoms of Roentgen sickness and compares them with the symptoms seen in certain diseases which are known to impair the

*From the Massachusetts General Hospital Boston Massachusetts

†Holmes George W.—Roentgenologist, Massachusetts General Hospital. Hunter Francis T.—Assistant Physician Massachusetts General Hospital For records and addresses of authors see This Week's Issue page 332

function of the liver, there is a striking similarity. For example, in catarrhal jaundice and in Roentgen sickness the earliest complaint is that of fatigue, then loss of appetite, anorexia, and finally, vomiting. That inhibition of function occurs after irradiation is generally accepted. This is particularly true of the glandular structures of the body, a well known example being the effect of irradiation on the parotid gland. The dose necessary to produce such inhibition of function is not large and hence it seems reasonable to assume that irradiation over the thorax or abdomen may temporarily inhibit liver function. It is also well recognized that an increase of carbohydrates in the diet or the use of glucose intravenously relieves, to some extent, the distressing symptoms often seen in acute impairment of liver function due to disease. It is largely on this assumption that we have adopted our routine of management of x ray sickness.

(1) *The management of "Toxic Sickness"*
The management of this group of cases seems obvious. The treatment consists in avoidance of large amounts of irradiation at any one time, particularly in cases with radiosensitive tumors. The initial dose should be quite small and every effort should be made to avoid a rapid breakdown of the tumor mass and the consequent rapid absorption of protein material by carefully regulating the daily dosage. Should very rapid absorption occur, on occasion true anaphylactic shock may take place, e.g., pulmonary edema, and the usual treatment for anaphylactic shock is indicated. When the symptoms seem to be more definitely those of toxemia, such as fever, leucocytosis, etc., stimulation of elimination, supportive treatment, fluid rest, and at times, intravenous glucose may be used to advantage.

(2) *The management of "Psychic Sickness"*
In this type of sickness prophylaxis is, again, more important than treatment. We do not believe that this type of sickness occurs except in persons who have previously been made sick by irradiation. If this assumption is correct, this type of sickness could be completely eliminated by careful dosage and proper selection of cases. If, however, it does occur and becomes unmanageable, it is at times even advisable to transfer the patient to another clinic, or to use a different form of irradiation such as radium, rather than high voltage x ray. Clinically this type, as we have noted before is characterized by rapid development of symptoms after or during treatment. In these cases the therapy should be given in the shortest possible time. It is surprising that in this group, as well as in true Roentgen sickness, the symptoms do not depend entirely upon the size of the dose given. Doubling the dose may not appreciably increase

the severity of the nausea or vomiting. In some cases of this type we have found it advisable to keep the patient under morphine and scopolamine, and to give intravenous glucose by the constant drip method, completing the entire treatment within forty-eight hours. Recovery from the sickness does not appear to be prolonged and it may be much easier for the patient than to be permitted to have anorexia over a longer period of time. As Pfahler has pointed out, this group of cases is very susceptible to odors which may be present in the treatment room. These odors may be minimized by using equipment so constructed that the tube and high tension wires are outside the room in which the treatment is given. In spite of these precautions, however, they are not always completely eliminated. When such a patient complains it is at times advisable to have him report early in the day, for even with the best equipment, after some hours of continued use there will usually be some odor present.

(3) *The management of "True Roentgen Sickness"*
If it is assumed that "true Roentgen sickness" is related to temporary disturbance of liver function by irradiation, there are certain routine measures which may be taken which may either prevent, lessen, or eliminate this form of sickness. Those patients who have recently undergone a major operation, those who have been for any other reason on a restricted diet, and those who are already nauseated from their disease are almost certain to develop "true Roentgen sickness". The condition of these patients should be improved as much as possible before beginning treatment. It is better to wait, after operation, until the patient is again on a normal régime, is taking liquids freely, and is able to take a reasonable amount of nonirritating food. It must be borne in mind that particularly in cases which have had abdominal operations, nausea and vomiting may be caused by subacute intestinal obstruction, and it is obvious that under such circumstances irradiation should not be begun until the abdominal condition has been surgically cared for.

In all types of sickness particularly in "true Roentgen sickness" where heavy, prolonged treatment is planned the carbohydrate intake should be increased. If possible, this should be begun two or three days before irradiation therapy is started. We have found that if a high carbohydrate diet is prescribed and the patient is given candy between meals and fruit juices sweetened with extra amounts of lactose, many patients may go through their treatment without any nausea or anorexia. If unable to take foods by mouth, at times we have given glucose intravenously before and during the treatment. The usual amount is 1500 cc. of five per cent glucose given twice a day by the intravenous drip method. The results with

this type of management have not been constant, but a sufficient number of cases have responded well enough to make us feel that it is of considerable value. In addition to the carbohydrate intake, it is important to keep the bowels moving daily, and to insure a good night's sleep, even if the use of sedatives is required. It has been our experience that when the cases are properly selected, carefully prepared for treatment, the proper dose prescribed to correspond with the patient's condition and with the size and location of the area treated, and a forced

carbohydrate intake maintained "true Roentgen sickness" rarely develops and we are able to carry most cases through their series of treatments without discomfort.

CONCLUSIONS

1. There appear to be three distinct types of Roentgen sickness (a) "toxic sickness", (b) "psychic sickness", and, (c) "true Roentgen sickness".
2. The prophylaxis and management of these three types of treatment have been discussed.

VORHEES BAG IN THE TREATMENT OF PLACENTA PREVIA*

BY MEINOLPH V KAPPIUS M D I

A STATISTICAL study has been made of all of the cases of placenta previa treated with Vorhees Bag at the Boston Lying-In Hospital during the period beginning with January, 1916 and ending with January, 1934. It was undertaken primarily for the purpose of affording comparisons between this and other methods of treatment for the same condition as carried out contemporaneously in the same institution, notably Braxton Hicks version alone or in conjunction with bagging, and Caesarean section.

This series includes 120 patients. Of these, nineteen had a complete previa, thirty-four partial and sixty-seven marginal. With few exceptions all of these patients were treated in a more or less routine manner on admission to the hospital. They were prepared for vaginal examination and under an anesthetic the finger of the examining hand was passed through the cervix and the inside of the lower uterine segment explored. There are, however, sufficient incidences of patients having been previously examined vaginally without inserting the finger through the internal os or rectally, and the presence of a placenta previa overlooked, to make it appear obvious that such an examination is not only misleading, but dangerous to the mother and child. That a serious hemorrhage was not precipitated reflects upon either the gentleness or inadequacy of the examination, or both. One patient early in the series who had two such examinations in the Out-Patient Department was later admitted to the hospital in poor condition following a third attack of bleeding, the last a profuse hemorrhage.

Only two patients were admitted with vaginal packs, yet all but thirteen patients were in good condition on admission and in only one was there profuse bleeding. Aside from its inade-

quacy, this would indicate the lack of need for such packing, with its probability of contamination, if patients are promptly hospitalized and then examined after any abnormal bleeding in the latter months of pregnancy.

Although dealing with patients varying in duration of pregnancy from five months to term, in only five instances is the cervix described as being closed, but in spite of this, it evidently admitted the examining finger sufficiently for diagnostic purposes. In the majority of cases the cervix was dilated two fingers or more, sufficient for the performance of a Braxton Hicks version if such method of treatment had been elected.

Bags varying in size from three to six inches in diameter were used, the larger sizes predominating. It is of interest that in the eighty-eight cases so recorded, the bag was inserted extra-ovularly fifty-two times, intra-ovularly thirty-eight times. There is nothing to indicate that the method of insertion influences either the blood loss incident to the bagging or thereafter. Bleeding is usually well controlled, as indicated by the relatively small number of transfusions before delivery—a total of six—especially when it is recalled that thirteen patients were in only fair condition on admission.

A rather unexpected finding is that the length of time until expulsion of the bag was forty-eight minutes less when the bag was placed outside of the ovum rather than inside, five hours and thirteen minutes as compared with six hours and one minute respectively. However, since the bag was removed slightly more than twice as frequently when the membranes had been previously ruptured or the placenta perforated, it seems probable that labor was progressing unsatisfactorily or, as happened twice, bleeding was inadequately controlled. It is also to be noted, in determining a choice of methods, that of the seventeen patients who bled after the bag came out or was removed thirteen had had an extra-ovular insertion. Incidentally, of the forty

stillbirths of all weights, twenty six occurred with an extra-ovular and only fourteen with an intra-ovular insertion.

TYPE OF DELIVERY

As shown by table 1, there were three sets of twins and one patient died intra partum mak

TABLE 1
TYPE OF DELIVERY

Version and Extraction	11	21	28	58
Total	20	35	67	120

Includes 3 pairs of twins (1 patient died, undeliv 1)

ing a total of 122 babies delivered. The preponderance of deliveries by version and extraction is noteworthy. It encourages three inferences (1) that labor was artificially terminated because of fear of hemorrhage, (2) that actual hemorrhage made delivery desirable or imperative (3) that the baby was, or appeared to be, in jeopardy. It is difficult to obtain statistical evidence regarding the actual degree of dilatation of the cervix when the bag was expelled but it is recorded sufficiently often in this series to leave little doubt but that a large number of babies were delivered before the cervix was completely dilated, if such terms as, 'almost fully' or 'full dilatable' are assigned their proper meaning. This has an important bearing on the fetal as well as maternal mortality and is a direct criticism of this form of treatment.

FETAL MORTALITY

Since the treatment in placenta previa consists in termination of the pregnancy irrespective of its duration any study of fetal mortality, to be of comparative statistical worth must of necessity consider not only the mortality in gross, but on a defined corrected basis as well, which requires also an analysis of results in different weight groups. A certain number of patients enter the hospital with dead babies. Some babies are obviously nonviable or present developmental deformities inconsistent with extra uterine life. It is inaccurate for statistical purposes to determine nonviability by arbitrary standards, as occasionally a small baby survives. This applies to a 2 lb 7 oz. baby in this series. For practical purposes, however and as a guide to treatment, a baby under 4 lbs deserves little consideration. To overcome the above difficulty, the fetal mortality has been computed separately for the different weight

groups and this permits comparison with the fetal mortality for a large series of babies delivered by all methods in the same hospital over a like period of years.

TABLE 2
FETAL MORTALITY

Weight of Baby	Central	Par-tial	Mar-ginal	Total	General for B. L. H.
Under 3	100%	100%	50%	90%	88%
3-4 lbs.	100%	100%	71.4%	83.3%	44%
4-5 lbs.	—	66.6%	63.5%	63.5%	5%
5-6 lbs.	66.6%	50%	33.3%	40.0%	3%
Under 4	100%	100%	75%	83.1%	—
Over 4	50%	33.3%	24.1%	43.6%	—
Over 5	44.4%	27.5%	14.2%	21.8%	12%
All Babies	64.3%	53.3%	33.9%	52.5%	—

The figures as shown in table 2 are entirely on a corrected basis, monstrosities and babies in whom fetal heart sounds were poor or inaudible on admission having been excluded.

It is to be noted that up to 4 lbs, 83.1 per cent of the babies were lost and this constitutes 34 per cent of the entire series of babies, hence different standards for the comparison would appreciably affect the fetal mortality as reported.

A comparison of the fetal mortality in babies of varying weights with that of similar groups for the entire hospital series indicates a striking discrepancy. Is the high figure in the former largely attributable to the type of delivery or to the underlying complication of pregnancy? There is clinical evidence to conclude that small babies in particular who have been subjected to maternal hemorrhage have a high death rate irrespective of the type of delivery. Yet, it seems reasonable that a certain number of these smaller babies, and most of the larger ones, could be saved by Caesarean section.

To determine the accuracy of this assumption a comparative analysis has been made of the fetal mortality in placenta previa when treated by Caesarean section¹ in contrast to Braxton Hicks version², and Vorhees Bag. In a few cases the last two methods were combined (Table 3). In arriving at the corrected mor-

TABLE 3
COMPARATIVE TOTAL MORTALITY

Method of Delivery	Caesarean Section	Braxton Hicks Version	Vorhees Bag
Total No. Patients	62	71	120

6	4	Marginal	Version and Extraction	Shock and Hemorrhage
7	4	"	Undelivered	Coronary Embolus
8	17	"	Braxton Hicks Version	Sepsis

died undelivered. She was admitted in good condition and at no time was there undue bleeding. No autopsy was obtained but the death was characteristic of coronary embolism.

Of the remaining seven, five died of hemorrhage, or shock and hemorrhage, and two of sepsis. Three of the former entered the hospital in relatively poor condition due to loss of blood. All five of the patients died within

five hours of delivery. In four, delivery was effected by version and extraction, in the fifth by breech extraction. Two patients in this group sustained lacerations of the cervix, which required suturing, two were examined for tears of the cervix and lower uterine segment but none found, while no mention is made of the other.

Of the two patients who died from sepsis, one had had two vaginal examinations under decidedly questionable conditions before admission to the hospital. The other was a patient who was admitted for bleeding of a slight amount and on examination a marginal previa was felt but no attempt was made to initiate labor. Two days later, the patient having slight pains without progress, a No. 4 bag was inserted, which was expelled the next morning. Evidently no further progress was made as a Braxton Hicks version followed by slow extraction was done. Considerable foul smelling lochia was noted and patient had a chill after delivery. The baby weighed 9 lbs 11½ ozs and was stillborn, the fetal heart disappearing a few hours before the bag was expelled. The patient died on the eighth day following a septic metritis, septicemia with abscess of the lung and embolic pneumonia.

Both of the deaths from sepsis occurred in patients having incomplete previas, whereas, all of the deaths in the complete previa group were due to shock and hemorrhage. This is comparable with Depken's statistics, which, in a series of 204 placenta previas, 114 of which were delivered with Vorhees Bag, show deaths in the central previa group as due to hemorrhage in eight and sepsis in one, whereas, in the incomplete previa group eight deaths were caused by a sepsis and two by hemorrhage.

SUMMARY

In a series of 120 patients with placenta previa, eight mothers died, five from shock and hemorrhage, two from sepsis and one from coronary embolism, a maternal mortality of 6.6 per cent. Twenty-four and five-tenths per cent of the patients had a febrile convalescence. The fetal mortality for all babies who had good fetal heart sounds on admission (exclusive of 2 monstrosities) was 52.8 per cent and for all such babies over 4 lbs, 43.6 per cent.

CONCLUSIONS

The high fetal mortality among viable babies indicates that the use of the Vorhees Bag should not be the method of choice when dealing with a live viable baby. This applies equally to premature, immature and full-term babies irrespective of the type of previa.

The 24.5 per cent morbidity, as compared with 5 per cent for all patients in the hospital, indicates the much greater susceptibility of patients

with placenta previa to infection and the two deaths from sepsis emphasize its relative importance in contributing to maternal mortality in this condition.

A comparison between the results following the use of the bag and those obtained by Braxton Hicks version alone or following the bag and Caesarean section, emphasizes suggestions for treatment previously outlined by Irving¹ and crystallizes the opinion that instead of allowing the type of previa encountered on examination to determine the method of treatment, all cases of placenta previa might better be considered as a group, all manifesting varying degrees of the same condition and the considerations determining treatment be limited to the condition of the patient and the baby on admission to the hospital, or when treatment can be instituted.

On such a basis the babies would fall into two groups (1) fetal heart sounds poor or absent or estimated weight of the baby less than 4 lbs (for practicable purposes non viable) (2) a living baby, weighing over 4 lbs.

The mothers can be subdivided into three groups (1) those in good condition, (2) those in poor condition due to loss of blood, (3) those potentially infected.

Mothers in good condition with a living viable baby should be subjected to Caesarean section in the interests of the baby, those with a dead

or non viable baby can be delivered through the pelvis by Braxton Hicks version if the cervix is two fingers dilated (rather than waiting for spontaneous expulsion of the bag and possible hemorrhage), then spontaneous delivery.

Patients in poor condition due to loss of blood are preferably delivered by Braxton Hicks version, or bagging and Braxton Hicks version, as it entails less shock than Caesarean section, permits a more effective method of controlling immediate blood loss and allows for an interval during which the patient's general condition can be improved by transfusion and other supportive treatment. The baby under such circumstances is not likely to survive, irrespective of the method of delivery.

This leaves for consideration the potentially infected patient who enters the hospital with a vaginal pack inserted under questionable conditions or following vaginal examinations carelessly made. Irrespective of the condition of the baby or type of previa the interests of this patient are best served by a Caesarean section followed by hysterectomy.

FRACTURE OF THE EPIPHYSIS OF THE LESSER TROCHANTER OF THE FEMUR

BY SETH M. FITCHET, M.D.*

FRACTURE of the lesser trochanter of the femur is a relatively rare condition or else rarely noted or reported.

King¹ was able to collect but sixty one cases from the literature. To these sixty-one cases, King adds one case of his own. The end results are known in fifty cases. Of these fifty cases, four died of other causes. Of the forty-six remaining cases in this series of fracture all recovered fully irrespective of the varied methods of treatment employed.

REPORT OF A CASE

History. A boy fourteen years of age was making a standing high jump. He is not sure how he took off for the jump but believes he landed first on his right foot and with his body hyperextended at the hips. As he landed he felt a sharp pain which he localized chiefly on the lateral aspect of his right thigh to the lower third. He fell to the floor in pain. He was assisted to his feet and was able to

walk with assistance but complaining of pain still localized chiefly over the lateral lower third of his thigh.

Physical Examination. He was seen that night but examination was not satisfactory because of extreme apprehension on the part of the boy. Flexion of the thigh while supine was possible actively and passively to about forty-five degrees without undue complaint of pain. Beyond that point he could not go because of pain referred to the lateral aspect of the lower one-third of his thigh. While sitting with his legs over the side of the bed he complained of pain in the same region and could not flex further (Ludloff's sign). Internal and external rotation were possible but painful. There was moderate spasm of quadriceps and adductor group of muscles. Abduction was resisted. Tenderness over all of the thigh was complained of but was believed to be due to his apprehension since there was no localization. There was no swelling or discoloration. The left side was normal.

Fracture of the lesser trochanter was not suspected. No rupture of muscle could be made out. "Pulled groin" appeared to be the probable diagnosis but did not satisfactorily explain the pain referred to the lateral aspect of the lower one-third of the thigh.

X-ray examination of the entire femur showed

Fitchet, Seth M.—Visiting Surgeon Orthopedic Department, Children's Hospital. For record and address of author see "This Week's Issue" page 322.

a fracture and displacement of the lesser trochanter, typically upward and medially, and no other pathology

Treatment A hip spica plaster cast was applied with the hip flexed at about thirty five degrees, neutral as to abduction and adduction, and extending only to the level of the patella

Exercises of the foot and leg and "setting" exercises of the muscles of the thigh were instituted at once and continued until the plaster spica was removed after being on for four weeks

As soon as he had regained his balance he began to get about on crutches. Crutches were used for one week, a cane for an additional week, and then he was permitted to resume normal activities

The x rays show the separation of the epiphysis

and a satisfactory bony union two months after the injury

The anatomy involved needs no comment except to remember that the powerful iliopsoas

muscle has its principal insertion into the lesser trochanter and at times must exert a very powerful pull on this insertion

Fracture of this epiphysis most frequently occurs between the ages of twelve and seventeen, before the epiphysis becomes united by bony union with the femur

In all the cases except two, or possibly three, studied by King, the injury was in males. Usually it occurs during sudden hyperextension of the trunk on the thighs during some athletic activity. Since girls are taking a more active part in athletics, it is quite possible that the girls will show an increasing incidence of this injury as time goes on

SUMMARY

- 1 A typical case of fracture of the lesser trochanter of the femur is reported
- 2 The injury is correctly termed an "athletic injury" occurring primarily in children before the age of bony union of the lesser trochanter with the femur
- 3 Diagnosis may be confused with "pulled groin" and entirely overlooked because of nerve distribution referring the chief complaint at a distance to the injury
- 4 X-ray shows a characteristic displacement in the direction of the pull of the iliopsoas muscle, which is, of course, the displacement factor
- 5 Because a small part of the combined tendon of the iliopsoas inserts into the shaft of the femur below the lesser trochanter, this displacement is limited in extent, since we have no evidence that this insertion is pulled off when the lesser trochanter is fractured
- 6 The epiphysis will reunite no matter what treatment is instituted, or none, even though the epiphysis appears widely separated
- 7 A logical treatment appears to be that of treatment of a fracture, immobilization in a plaster hip spica, in moderate flexion, neutral as to abduction and adduction, with the leg free to permit active exercises, with the usual routine of after-care employed in the treatment of fractures

THE NEW HAMPSHIRE MEDICAL SOCIETY

MEDICAL ECONOMICS*

BY N. B. VAN ETTEN, M.D.†

"PUNCH, my dear Copperfield, like time and the tide, waits for no man," said Wilkins Micawber whose attitude of expectancy toward fortuitous circumstance is typical of large numbers of physicians today. Waiting for something to turn up may be characterized as dignified and masterly inactivity, but it will prove as disastrous to medicine as it was to Micawber. I fear that some very potent punch must be served to the medical profession if it shall ever be awakened to an appreciation of its collective responsibility.

Scientifically, medicine is glorious. Economically it is improvident. Living in an industrial age it makes little effort to learn from industry practical methods for spreading the knowledge of its potentialities. Hiding its light under obscurant ethics because of fear of commercializing individual abilities, it screens from publicity much knowledge of great popular value. Membership in a profession seems to have caused the physician to forget that everything in this country moves to the tempo of industry.

We struggle for employment or fall into the mass of those who cannot keep up with modern rhythm. From birth to death we all live by the clock. The physician rates no exception. The compelling pulse of progress beats also for him. If he fails he cannot eat, cannot pay his rent, his fuel bill, his taxes, cannot insure himself a decent interment.

If modern society rates him successful, he must step faster and sleep less than others. He cannot be content with being on time, he must be ahead of time. For many of us 1934 and 1935 have been a whirl of desperation of anxiety of speculative wonderment. The Doctor of Medicine is accused of being socially uncooperative and out of step. The Doctor of Philosophy is now trying to prescribe. Will the American people take his medicine? The bottle is labeled Socialism and State Medicine. The directions are, take it and like it. Socialism is defined as a theory of civil policy that aims at the public collective management of all industries. Socialized Medicine would be the public collective operation of the practice of medicine.

State Medicine is the operation of the functions or powers collectively of a state or nation in the control of the practice of medicine. These forms of collectives are claimed by their advo-

cates to promise sure cures for all of the present economic troubles of the physician.

The struggle between individualism and collectivism is world wide. The Soviet steam roller has been unsuccessful in ironing out the rising tide of capitalism. The Soviet tractor has failed to eliminate man power individual farms producing a bushel an acre more than the highly mechanized State collectives. The German State has not profited from the murder and exile of German individualists and I am told that the German physician has sunk to new lows under their present system of State Medicine while misery, malingering and misrepresentation have risen to new heights. Fifty years ago students of medicine pilgrimaged from every corner of the earth to the feet of the German masters of science. No one goes now. The masters have been ruined by mass medicine and finally have been scattered by the lash of paganism.

A distinguished German professor under the date of March 10 1935 writes "I hope that the curse of Health Insurance will be spared to the profession in the United States. It is the beginning of the end of independence and high moral standards. It has ruined the profession all over Europe." Before the institution of Health Insurance the German people averaged five and one-half days of annual sickness, a rate which has now risen to twenty five and one-half days. This is a false index of morbidity because much of it is due to false certification by a demoralized medical profession. Contrast this with seven days annual sickness in the United States.

The American physician is having plenty of trouble, but at the same time is still giving the highest quality of service of which he is capable and better service than is given in any other country in the world. It cannot be denied that American physicians are themselves measurably responsible for their difficulties, that those who have been making a living have not been properly interested in those who have not. It cannot be denied that the workers in Organized Medicine have been retarded in their work by a very large number of physicians who are so indifferent to their own welfare that they do not take the trouble to attend the meetings of their County Medical Societies but, while being entirely uncooperative, do not hesitate to rovilé their officers for involving American Medicine in an economic crisis.

It cannot be denied that conservative doctors, indifferent doctors, lazy doctors, foundation

*Read at the Annual Meeting of the New Hampshire Medical Society at Manchester, N. H., May 1, 1935.

†Van Eetten, N. B.—speaker, House of Delegates of the American Medical Association. For record and address of author see "This Week's Issue," page 322.

doctors, dissatisfied doctors, unethical doctors, socialistic doctors, communistic doctors, doctors of Public Health, doctors of Philosophy, are all taking a shot at Organized Medicine

The conservative doctor resents the suggestion of any deviation from the traditions of medicine, any new plan for the payment of the doctor. He has nothing to offer but his satisfaction with things as they are

The indifferent doctor does not care enough about economics to go to his County Society meetings and thinks the evolution of *laissez faire* will take care of things and that everything will go on about as usual, and that there is nothing he can do about it anyway

The lazy doctor, who is largely responsible because he is so socially uncooperative that he has taken no interest in the fact that lay organizations have taken away from the doctor the administration of several fields of medical service, notably that of tuberculosis and mental hygiene, will wake up long enough to ask why his elected representatives have permitted such an outrage upon the medical profession

Then there is the doctor who is under such obligation to philanthropic foundations that he no longer speaks the language of the County Medical Society. He is so saturated with the social theories that are backed by rich laymen who employ doctors of Philosophy to do their thinking, that he has come to believe that medical organization is unimportant. He has no plan of his own but is willing to impose a copy of some of the foreign plans which are now regarded as unsatisfactory in the countries in which they are now operating. He is willing to impose those systems of the delivery of poor medical care upon the American people. He says that Organized Medicine is on its last legs and is now fighting a losing game with its back to the wall. He may be right. The strength of wealth accumulated through the devious control of useful everyday commodities by capital combinations may buy political control of an idealistic profession and destroy its value to the people and may dull its scientific interest. Some of these foundations have promoted valuable scientific operations, but it is an interesting fact that no great discovery has ever been evolved from these groups. Always and only the individual, by lone concentration of his energies, has produced the real discoveries that have changed and advanced basic science

Then there are the doctors of undefined desires, who are dissatisfied with the status quo, which a colored clergyman defined as, "the mess we is in". Vulnerable doctors who try to justify themselves by asserting that everybody is crooked, all "merchants of health", all fee-splitters. They claim that medical ethics are mere façades to cover criminality, abortions, fraud and deceit. They would reduce everybody to their own depths of intellectual dis-

honesty. While they claim that Socialized Medicine will furnish panaceas for the plight of medicine, they merely mean that they see, in such operations chances for their own parasitical existence

Organized Medicine on the other hand, is trying to furnish constructive plans for the delivery of better medical service to all of the people and protection of the physician from bureaucratic domination. One hundred and fifty different operations are now proceeding in the United States, some of which are thirty-five years old. None of them involve either voluntary or compulsory insurance, but all of them are attempting to keep the patient in the hands of his personal physician and out of the hands of government

The exigencies of the times demand the full cooperation of every licensed practitioner of medicine. Medical organizations have been too conservative. In order to avoid mistakes all of the units of Organized Medicine must work together, not only to resist the imposition of regimentative schemes upon the medical profession, but also to evolve plans which will satisfy the demands of society without sacrificing the dignity inherent in the delivery of service of high quality

The American physician is entitled to an opportunity to advise and to propose any legislation concerned with the health of the American people. Change comes to the physician and he will welcome it. Social conditions change the manners and the conduct of all professions. The medical profession asks that its educational qualifications be taken into account in the development of new programs for medical service. The prospect of legislation for control of the delivery of medical service being written by lay foundation employees is a dismal one and should be vigorously protested

The continued activities of some of the foundations have served a useful purpose if they have sufficiently irritated the medical profession to stand upon its own feet and repudiate the offensive actions of those non-medical dilettants, who assume such superior knowledge of what is the best medicine for the American people. Private practice has such public consequence that there is need for Government umpiring, but the prospect of Government competition is appalling

In the light of debasing foreign experience with State Medicine and in the light of our own experience with political bureaucracy, the physician who respects the high calling of his profession must meet the threat of an extension of State Medicine as a militant fighter for the maintenance as well as the elevation of his ideals. It will be a backward step into chaos if the Department of Labor of the United States should succeed in imposing upon the medical profession codifications such as those which have cre-

ated such confusion in industrial and agricultural production

How shall the sick be adequately served? How shall the servants of the sick be adequately paid? These are the questions which should be adequately and unemotionally debated in every State and in every County before burried national commitments are made. Quacks, charlatans and cultists have always marched side by side with the physician, and occasionally politicians notably Bismarck and Lloyd George, have joined the long procession of those who have discussed these questions.

For a long time professional philanthropists have theorized and politicized, using physicians as unpaid pawns in their schemes of health promotion. They have promoted large scale institutional care of the sick with more or less success because the physician was always willing and anxious to be exploited. The physician, always dominated by scientific interest, was more concerned with the welfare of the patient than with his own comfort or prosperity. He has been improvidently generous.

All of modern medicine has been developed within the last fifty years, and the progress of the science of medicine has been so absorbing that the art and application of medicine has lagged far behind, and shows few signs of reaching its proper proportionate position unless or until a new type of physician shall have been developed. The physician now feels the pressure of Public Health education, and the reaction of his own work in preventive medicine which has eliminated diseases which formerly absorbed much of his effort. The physician has cooperated with the Government agencies in the attempt to eliminate communicable diseases and the absence of destructive epidemics has been of great economic value to the Nation. Unpredictable catastrophes have always been cared for by Health Departments, or by emergency organizations supported by generous people and by the free services of physicians with the hearty concurrence of the whole profession. The quality of medical care has been so remarkable that students generally concur in the opinion that nowhere are the citizens of any country better served.

The United States Public Health Service reports for the year 1933, the lowest general death rate ever recorded for this Nation. The Division of Vital Statistics of the State of New York reports for the year 1934 the lowest death rate for the State since such figures have been collected, "11.1 per 1000 of population." Infant mortality under one year was 52 deaths per 1000 live births. This figure has never been lower. The maternal mortality rate of 50 deaths per 10,000 total births was, with the exception of the rate for 1916, the lowest ever recorded. The scarlet fever rate was 1.2 per 1000 the second

lowest recorded. New minimum rates were set for typhoid 0.6, tuberculosis 56.1, pneumonia 83.9, influenza 6.7 and cerebral hemorrhage 48.6. The total number of cases of diseases reported was lower by 40,000 than in 1933.

Such statistics do not support the claim made by some advocates of Social Security programs that large numbers of the American people receive no medical care. The fact that all morbidity and mortality statistics show general decline, except those relating to senescence and casualty, materially changes the health picture of the Nation, and confronts the physician with radically different medical and social problems to which he will be compelled to adjust himself individually and collectively.

The distribution of medical care, while admittedly faulty, is steadily improving. In New York State a few years ago, there was attempted a campaign for remedying the rural situation by planting physicians in small towns where there were no physicians. The few physicians so placed could not exist in those small places because the rural people drove right past their doors to the larger towns where they thought that they could find better medical facilities. In short, good roads largely solved the rural medical deficiencies in the State of New York.

In spite of the fact that very few physicians have ever been included among the wealthy classes, there has been very little complaint from physicians until the last five years. In our richest year 1929 only fifteen per cent of the physicians had net incomes above \$10,000 and this group was largely composed of highly skilled specialists. At the other end of the financial scale fifteen per cent were said to be failing to make a living. As this was in our most prosperous season this fifteen per cent may safely be considered a constant figure and it is reasonable to assume that this group includes not only aged and physically incompetent physicians, but also those unkindly treated by fortuitous circumstances, and those who lack the will to work. During the present depressive cycle it is said that thirty per cent of the physicians are failing to make their current expenses.

Many limited specialists suffer extremely because many of their patients are unable to pay the specialists' fees and have returned to their family physicians or turned to free clinics. For several years physicians have complained of the intrusion of free or cheap clinics upon their private fields. They have complained of the corporate practices of institutions in delivering medical care, because in line with all corporate practices they have crowded out the small individual by restraint of opportunity. During this time physicians have continued to be the only double taxpayers concerned in the care of the sick making their regular tax contribution and at the same time serving tax-supported

institutions and public clinics without fee. In all of this public service, physicians are the only persons who work without pay. This inherited traditional service has now become so heavy that the physicians are stimulated to demand a change. If, however, economic conditions should tend to improve it will be characteristic for physicians to continue to give away millions of dollars in free service.

It has been claimed that the only way to secure payment for the physician for his free work is through the medium of sickness insurance. May I remind you that the foreign insurance schemes, as now operating, provide for workers only and not at all for the indigent who must be cared for by general taxation. The taxpayer pays nurses, social workers, and all other hospital servants. Because the physician is a higher grade servant of the sick, delivering a higher grade or quality of service would not seem to justify the taxpayer in expecting him to work without pay in a tax-supported operation.

There were more than 450,000 separate visits to the city hospitals in the city of New York during the past year, 1934, made by visiting physicians and surgeons. For this vast service not a cent was paid by the city of New York or by any one else, 2,290,000 treatments were given in out-patient departments to approximately 500,000 patients. These figures do not include an additional very large figure for the free service of physicians in the non-governmental hospitals which would have been obliged to close their doors if this free service had been discontinued. Who are asking the Government to interfere in the practice of medicine? Who are devising schemes for security through insurance or cooperative protection of medical service? The visible demand for Government medicine seems to come from the patrons of free hospitals or free clinics. The medical indigent, who may be defined as a person who cannot pay for medical care without denying himself or his family the necessities of life, is entitled to this care, but the generosity of the taxpayer is abused by a very large number of people who are well able to pay for the same kind and quantity of care they seek in the hospital.

Otherwise I do not hear people asking for free service. I see no letters in the newspapers complaining of the quality of medical care. There seems to be no public demand for Sickness Insurance. Public officials are not besieged with cries for public medicine. The common run of people seem to be satisfied with the medical care they now receive. Large groups such as the Parent-Teacher Organization or the Labor Federations are not asking for Sickness Insurance. Labor asks for equitable wages and if, or when, labor secures them there will be little or no demand for any type of compulsory Sickness Insurance.

Our people are entitled to good medical care. Physicians want to give it, but are met with the resistance of indifference. This is well illustrated by the reaction of the people to campaigns for immunizations, which show only half-hearted cooperation under the stimulus of artificial excitement, and show that no lesson has been learned of the value of the health measure because, after the health campaign is over, immunizations of the untreated are neglected just as they were before. People want security, so do physicians.

Physicians want to be paid for what they do. Not necessarily single fees for single services. There is nothing new about an inclusive fee for a complete maternity service. There is nothing new about agreements for a term of service. Deferred payment is not new, doctor's bills are usually put in deferred files.

Many medical service plans are being tried. The Iowa plan is still developing in that State and some of its features are being used in other places. Other notable plans are the Alameda plan, the San Diego plan, the Vaughn plan now being tried in many cities, and the Wayne County plan which is interesting many County Medical Societies. None of these plans employ compulsory or voluntary insurance and all of them are designed to give the patient the benefit of the services of his own physician.

If these plans, or parts of them, work well they may be tried without committing the Government. If they fail they can be forgotten. The new plans of the California State Medical Society go practically all the way to compulsory Sickness Insurance with all of its governmental complications. If the Government sets up a machine to develop a system of service it must employ many people. It must pay them. The Legislature that votes the money must participate in its spending. If they spend money, bureaucracy is inevitable and, once embarked upon, is almost impossible to recall if it proves to be inefficient.

Who is asking for Sickness Insurance schemes built after the European manner? Or any other schemes which involve the necessity for permissive or mandatory legislation?

A group which is actively demanding Socialized Medicine is typified by a physician who calls himself a "Merchant of Health who boasts superior honesty in admitting high pressure salesmanship" in order to increase his practice. In a public letter to which he signs his name and address, he asserts that "thousands of x-rays are taken needlessly for no other purpose than to help the doctor to cover his expenses." He continues, "How many injections of one kind and another, how many laboratory tests, basal metabolisms, electrocardiograms are done daily when the physician knows beforehand that the reports will be negative, but makes the patient

take those tests for no other reason except the monetary reason? How many patients are referred to consultants and specialists so that the general practitioner will get his half, third, or quarter of the fees collected, depending upon the particular specialist?"

He denies that there is any such thing as a personal relationship between physician and patient and further continues, "Let us stop pretending and face the facts. Is there any one that does not know the general practitioner's very existence depends to a great extent upon the rake-offs he gets from referring his patients to various specialists and laboratories? His remedy for these disgraceful conditions is the socialized operation of the practice of medicine when there will be no cheating when everybody will be compelled to be honest by the order of the State. Everybody will be amply salaried and have no worries. How can highly educated physicians, who have spent half of their lives struggling to enter the practice of a supposedly honorable calling, subscribe to such pernicious utterances in the name of 'common honesty'? I know that there are a few physicians who are false to their oaths, false to their obligations as citizens, and the profession should be purged by their expulsion."

Another group of physicians who seem to desire Government medicine, are those who are already in it as practitioners of State medicine. Health officials who see an enlargement of opportunity in widened fields and employment in many bureaus. Few salaried officers can have a private practitioner's viewpoint, security colors their vision. Not a dazzling color however, because the average Government medical employee receives so small a salary that it excites very little envy.

The most ardent advocates of Sickness Insurance are foundation directors, who have never practiced medicine, who cannot understand the confessor relationship between patient and physician, and who desire in their great wisdom to prescribe English medicine, German medicine, or Red medicine for the American people.

Our experience with the operation of compulsory industrial insurance has taught us that it is riddled with rackets. A few physicians who are on the inside of the rackets, make inordinate profits while the rest of the profession and the injured workman got little or nothing out of this politically mismanaged piece of Government medicine. The contemplation of compensation operations will not inspire anyone to desire new forms of compulsory insurance until this present compulsory scheme shall have been so amended that labor, industry, and the physician shall be guaranteed and receive a fair deal.

Amending legislation to eliminate some of the medical abuses passed the New York State Leg-

islature at the last session, putting the selection of the physicians who may do compensation work in the hands of the County Medical Societies. Let us hope that the County Societies will rise to their new obligation so successfully that the Legislature will continue to listen to their demands for corrective legislation.

Although it may be possible that the insurance principle may be invoked in a final working plan for American medicine, let us avoid compulsory Sickness Insurance until every phase of the subject shall have been studied carefully and unemotionally with special reference to its adaptability to conditions of medical care in America.

Conditions of medical care have always been better in the United States than they were in England when compulsory Sickness Insurance was adopted there in 1911. National insurance appears to have improved the kind of medical service then given the British people, but Sickness Insurance there today does not prevent disease, does not take care of the indigent or reduce the costs of the care of this class of people and does not reduce morbidity. The average yearly sickness of the British people before 1911 was seven days, it has been extended to seventeen days and is another false index due to false certification and malingering. Sickness Insurance has not reduced the costs of medical care but has merely instituted additional expenditures incident to the collections and to the distribution of these costs.

The Organized Medical Profession has been called reactionary, and static, and obstructive, because it does not welcome these foreign schemes with enthusiasm. These aspersions are unjust. The Medical Profession knows that changes in the delivery of medical service are as inevitable as the changes due to the extension of scientific understanding of disease. The profession is willing and anxious to promote changes, ardently desires improvement in the art and application of medicine, is generously public minded, desires only the best of medical service for the American people, and asks that no governmental system shall be developed without full opportunity for free coöperation by American physicians.

During the last eighteen years there have been presented from time to time at the sessions of the House of Delegates of the American Medical Association various propositions concerning Sickness Insurance, and many forms of group or corporate or contract practice. All of these were seriously considered by reference committees and by the House of Delegates with an open mindedness and a forward looking vision which displayed intellectual integrity. The insurance schemes have been all disapproved and constructive cautions have been given concerning contract alliances involving medical practice.

The American Medical Association suggests uniformity of action in setting up its ten-point basic principles, but has no desire to suppress the spirit of adventure which may inspire pioneers to look for new paths to new horizons. Our present economic policies will not determine the course of the world of tomorrow, indeed it is much more likely that some now unknown influence will change the current of our civilization.

The World War failed to make the world safe for democracy. Its great accomplishment is a seventeen year armistice during which the World has rearmed as never before in history. Democracy is on trial. Dictatorships of various colors are dominant. America must walk carefully if she will avoid the "isms" that are keeping European Nations in constant fear of explosion. Regimentation is the parent of "isms." The threat of bureaucratic domination must be opposed. Self-respect must be maintained by maintenance of a high quality of service regardless of material reward.

It is evident that Organized Medicine must array its forces aggressively, not only to improve the service to the sick, but also to improve the financial position of the physician. American ingenuity should be equal to the task.

American Medicine has a task. It must not only defend itself against destructive influences, but also must develop a constructive offensive behind which all of its forces must be massed. One of its first objectives may very well be seeing that the physician is paid for his free work which he has imposed upon himself so long that society in general, and hospital society in particular, has come to regard it as his obligation. Getting the physician paid for his work may involve a revolution in hospital organization, it may involve cooperative or other insurance schemes, it is likely to be a key which may be difficult to turn in a rusty lock, but once turned may open the door to hitherto unsuspected opportunity. I believe that the time is ripe to try it. I believe that the state of the country justifies it.

A current historian of excellent repute stated a few days ago that, at this time, in spite of our confusion and economic distress, the effects of which are keenly felt by most of us, there is greater general economic well-being in the United States today than has been enjoyed by any other nation at any time in history. It is difficult to believe this statement in the light of your personal experience, and yet there is statistical evidence to support it.

A sense of confidence in future security would be justified if the country could be allowed to follow in natural ways its upward trend, if fear could be lifted, and if the genius surrounding the central administration could be tempered by sanity. If they could be infused with some sympathy for the present and fu-

ture taxpayers who must pay for the highly exciting music to which these geni are dancing.

While I believe that the Government pump priming is a retarding influence, I also believe that it cannot stop natural recovery and that the next decade is full of promise for those who have the will to work for the common good. The implication is especially pertinent to the economic situation of physicians who must drop all differences and work together.

Few physicians have ever acquired wealth from the practice of medicine. Many physicians are unable to maintain the overhead which they built up during the speculative decade of 1919 to 1929. Many physicians are failing to make respectable livings. Many physicians observe an increasing flow of paying patients to free hospitals. Many physicians are excluded from the opportunity to practice their profession in tax-supported hospitals.

Many physicians are on the outside looking in and will remain there until they unite in a demand as taxpayers for their right to participate in all of these public operations.

Fewer people are sick. Morbidity statistics are lowest in history. Fewer people are earning enough money to pay physicians. Fewer people are able to pay reasonable fees. Fewer people are able to pay any fee.

More people than formerly are visiting all sorts of cheap clinics. More counter prescribing by pharmacists prevails. More people eagerly accept and apply to themselves the medical advice of the radio broadcaster.

More patent medicines are taken. More physicians are being licensed than can be used by our citizens even if they were able to pay them, 125,000,000 people are served by 154,000 physicians, a ratio of 1 to 814.

The community is poorly served by crowded clinics. The community is defrauded by clinic visitors who are able to pay private practitioners. Community hospitality is abused by irresponsible non-residents. The community suffers from division of hospital support by too many hospitals or clinics too closely located.

The community has a poor return from its investment when hospital facilities are idle because of exclusion of practitioners who are qualified to use them. The community is poorly served by hospital practitioners who are disinterested because they work without pay.

All of these conditions can be cured by the concerted action of physicians, hospitals, welfare organizations, Health Departments, and an educated public.

These conditions cannot be cured by the imitation of any of the European systems of distributing medical care. They must be taken care of by ourselves, within our own medical organizations, and by the influence of sympathetic citizens.

By limiting the number of physicians newly licensed so that it may be possible for every com-

petent physician to make a living By zoning cities and communities so that they may be served by small hospitals By opening all tax supported hospitals to all physicians who live within the hospital zone

By payment of physicians for their work for the indigent in all tax supported institutions By payment of physicians for their services to all tax supported indigents within or without hospitals

By exclusion from tax supported hospitals of all non-emergent patients who are able to pay a private physician

By reform of the workman's compensation operation of compulsory industrial insurance in the interest of the worker and of the physician who takes care of him

By development of the full values of Organized Medicine by the enlistment of every physician within the ranks of the County Medical Society

By development of the values of the personal and family physician as the basis of medical service By maintenance of the highest quality of medical care

His age old experience and his education qualify the physician to meet a changing world and should qualify him for wise leadership of its evolution The future of medicine challenges him If he becomes indifferent, selfish, lazy, socially uncooperative, he will write a sad chapter in medical history, if he becomes alert, awake to his opportunities to meet the new daily demands of the American people and give the most faithful service, the service of personal devotion to the science and the art of medicine, his glorious traditions will be multiplied and he will meet the new day in the spirit of the old Sanserit Salutation of the Dawn,

"Listen to the Exhortation of the Dawn!
Look to this Day!
For it is Life the very Life of Life
In its brief course lie all the
Varieties and Realities of your Existence
The Bliss of Growth
The Glory of Action
The Splendor of Beauty
For Yesterday is but a dream
And Tomorrow is only a Vision,
But Today well lived makes
Every Yesterday a Dream of Happiness,
And every Tomorrow a Vision of Hope
Look well therefore to this Day!
Such is the Salutation of the Dawn

DISCUSSION

PRESIDENT LORD I will ask Dr Timothy F Rock of Nashua to discuss this paper of Dr Van ETTEN's

DR. TIMOTHY F ROCK When I was asked to discuss Dr Van ETTEN's paper I was very naturally embarrassed because I realize that it would be presumptuous on my part to attempt it and I felt that whatever I might say would be an anticlimax upon a most interesting and instructive presentation of the subject by an authority We are all greatly indebted to you, Doctor

I appreciate that the Doctor has given most generously of his time and talent to study and analyze an abundance of information and of misinformation upon the subject of Medical Economics or Socialized Medicine or whatever you may wish to designate State Medicine and has tried to separate the good from the bad that those who wish it may have a clear concept of the subject and that as much of State Medicine as may be forced upon us shall be made as distasteful to the profession as possible.

This Society appreciates the conscientious and tireless work of your Committee of the House of Delegates to preserve and buttress the profession against the insidious advance of the political control of the practice of medicine because such control unbridled may become political despotism I feel that I express the hope of this Society and of the thinking people of our State that the President's Committee on Economic Security at Washington shall be persuaded that relief of human suffering through sickness and the ministrations and administration of medical service shall continue to be the responsibility of the medical profession free from any group politically conceived politically born and nourished and maturing powerful and arrogant to our disadvantage by the spending of political favor for which we shall pay an unjust tax.

I am sure it has become a commonplace to feel that those in Washington have the answers for all the questions upon all of the problems of the day and that it is "Love's Labor Lost" for us to attempt to maintain the practice of medicine upon the high ideals of individual scientific initiative professional ethics and patient and physician relationship of the past if it fails to square with the New Deal program But I am not so sure that the New Deal answer to our problem is correct. It may be that Socialized Medicine or any other form of compulsory sickness insurance which makes for a mighty political influence while making near serfs of the doctors and drones of the willing people is not the right answer to the problem of Medical Economics.

State Medicine co-called seems to have had its start in Germany in 1883 when Bismarck initiated it solely as a sop for political unrest. It was introduced in England in 1911 by Lloyd George also as a stop-gap for political unrest. Wherever it exists its background is the same. Even in industry sickness insurance whether contributory or not, is fundamentally a political factor against industrial unrest. And whether you recognize it as such or not we have State Medicine in this country today and in this State and whether it is called Welfare or Federal Emergency Relief Administration or Economic Security or anything else its purpose is unchanged and its dangers every bit as pernicious and malignant as State Medicine in any form anywhere.

I presume that all of us realize that in England where State Medicine is perhaps less in disfavor among the physicians than in any other country the average annual income of all panel doctors is \$2000 out of which must be paid the usual expenses of a medical practice and that this income is greater than in other countries having State Medicine. While it is true that a panel doctor is permitted to have a private practice in addition to his insurance work few have the time for any such practice.

If that, or anything resembling it, is what now thought in this country wants, we have it and like it. You realize also I think that State Medicine or insurance practice means mass treatment, the couch and the bottle. If that is what the people of this country are willing to take they may get it. If unemployment relief is made a part of any medical prescription the multitude of poor souls too ill

to work will increase many fold, just as industry finds a disconcerting incidence of disability among those entitled to sick benefits as against the better health of those not so privileged and a dramatic recovery from disability, beyond the power of medical science, when benefits cease.

If these are among the fundamental goals of Economic Security that are to be saddled upon the backs of the people of this country, they may be achieved most speedily through State Medicine, or Socialized Medicine, or any other catch phrase designation you wish applied to a politically controlled practice of Medicine.

Vital statistics do not reveal any dramatic decrease in mortality or morbidity in Hillsborough County of this State in the last year or so. Yet the cost of medical care put upon the county has increased from an average annual expense of \$3000 up to two years ago, to \$40,000 last year. And for what? Sickness among our people has not increased to that extent, any more than that outlay has improved the health and happiness of our people. And the worthy poor were always adequately and conscientiously cared for.

It would seem that a system is developing similar to that in Germany where the number and remuneration of executives, social workers, clerks and others engaged in the care of the sick, far exceeds the number and the recompense of the doctors who treat them. It is not impossible that State Medicine, now an actual, vital, living thing under the Federal Relief Administration is, or will become, the kind of State Medicine which the most thoughtful element in the profession has long and earnestly opposed.

I do not intend the inference that there is nothing good for anybody in State Medicine as it lives today in this State, nor do I feel that every doctor and every citizen will view it, eye to eye, with me. I feel very strongly, however, that whatever of good there may be in it today is unreal and obscures its ultimate disadvantages to the physicians, professionally, scientifically, and economically obscures its degrading influence upon the morale of our people, and obscures the stifling burden which taxation for its wasteful operation will put upon all business and upon all the people.

Out of our experiences with State Medicine as it is practiced in this State, and I repeat that it is State Medicine, a segment of our profession may be economically encouraged because some recompense accrues from a service that would otherwise be gratuitous. This may simulate a feeling of security. Let me repeat, however, what I have said before, that herein lies a real danger to the whole profession, because the State politic and the citizen may become accustomed to medical service at a cost that does not and cannot repay the doctor for the careful conscientious attention he should devote to each patient, and these may well demand medical service at the same cost in a better day. It is also conceivable that present payments may be reduced as politically conscious administrators need to curtail expenses or look with envy upon the rising income of the physician as his number of calls ascend just as they have always done under similar systems subjected to the human impulses of doctor and patient alike.

When the time comes, as it came under every system of State Medicine, that the doctor is placed upon a wage or per capita basis, he may find his average payment something like *five cents* per call, as it has just worked out to be in a Massachusetts community.

I have it upon the word of physicians engaged at the present time in insurance work and in industry, that the amount of work, often to the point of

fatigue, demanded of them in return for their more or less security of income, stifles initiative and deprives them of the opportunity for self improvement. Such is generally the experience of panel or insurance doctors in their countries, such may well be the unhappy lot of those of us who feel complacent toward our present form of State Medicine, unmindful of the cancerous nature of its germ cell left unguarded.

We must put forth every effort and power at our command to the end that the practice of medicine under any form of political subsidy shall end with the emergency responsible for its birth. Let us hope that out of all the chaos surrounding the subject of Medical Economics some plan, that will be fair and just to the patient, to the physician, and to all the people who pay the bill, will be designed eventually.

All of us who are zealous for the future of our profession, that its ideals may continue and its achievements multiply for the benefit of all within our borders, rich and poor alike, hope that the practice of medicine may be allowed to live as an honorable profession, free from political influence or control, that it may not become a program of the cough and the bottle, or be divided in first and second rate doctors.

We thank you, Dr. Van Etten and your Committee, for your diligent work in our best interests.

PRESIDENT LORD: I will ask Dr. Metcalf to continue the discussion on this interesting subject of "Medical Economics of 1935."

DR. CARLETON R. METCALF: Your Committee on Legislation, which has had under its wings the problems in medical economics during the past year, has been concerned about possible adverse legislation, both from our own General Court and from Washington.

The legislation which concerned us most here was the so-called Epstein Bill, a radical bill for health insurance or sickness insurance, which was, in reality, introduced into the Legislatures of more than twenty states this past year. This particular bill came from an organization called the American Society for Social Security, which has about five thousand members, and which has its headquarters in New York.

We estimated that if this bill were passed in New Hampshire, it would cost about six million dollars to provide an inferior brand of medical practice in a state where the medical cost at the present time is about three million dollars. If any of you are familiar with bureaucracy, I think you can imagine what was going to be done with the extra three million dollars. When a group of five thousand enthusiasts try to put something over on the other 120,000,000 people in the United States, it looks to me like a very shining example of the tail trying to wag the dog.

This bill was not introduced in the New Hampshire Legislature, and while Dr. Van Etten and his colleagues in New York State have been locking horns with Mr. Epstein, we were ignored. So there are some advantages in being an inconspicuous state.

The other thing that we were concerned about was government ownership of medicine, emanating from Washington. It seemed to us that the more abundant life, which is about to be bestowed on the citizens of this country, was coincident with a less abundant life for physicians.

Your committee tried to counteract these two methods of legislation by talking before the county societies, by giving radio talks, by sending out releases to the newspapers and by an effort to affiliate with other groups who were similarly concerned.

—with the dentists with the 65 000 farmers in New Hampshire, with the employers and with the employees.

Your committee objected to first, compulsory insurance secondly insurance controlled by the government and thirdly the supervision of lay officials. You will find that those are the three key stones of all systems of medical insurance in the different European countries compulsion government control and lay supervision.

Your State Society and your House of Delegates followed the A. M. A. in a constructive program, which could be controlled and supervised by the doctors. But they tried to point out the dreary inefficiency of the systems which prevailed on the continent of Europe.

A few weeks ago I had the pleasure of talking with Dr. Gros, who is in charge of the American Hospital in Paris and I asked him how the French system was working out. He said that the doctors didn't like it and that the patients didn't like it. He told me that he had to contribute \$15.00 a year for his cook, she had to contribute \$30.00 a year and the government contributed another \$15.00 a year a total of \$60.00 a year. Recently his cook injured a finger she went to the clinic to have it fixed and sat around several hours before a young doctor came out and put a splint on the finger. He said I lost her services for six hours. I am going to hire one of my friends and pay for it myself the next time she hurts her finger.

Our efforts may have met with some success. Both of our Congressmen at any rate seem to be with us. Our former Governor and present Congressman, Charles W. Robey has written to me

"I have for some time, been interested in some form of old-age pension and unemployment insurance and have been sympathetic therewith. I believe these two salient points are real objectives and the matter which you oppose namely sickness insurance I shall oppose if an opportunity comes to vote against it.

Congressman Rogers wrote in a similar vein

Now I think it is obvious from what you have heard today that it is up to us to present a united front on this matter. And I hope that every one of you will impress the views of the medical profession not only on your patients but on the respective members of the largest legislative body in the world.

PRESIDENT LORD Does Dr. Van Etten wish to add anything to what he said?

DR. VAN ETTEN Mr. President—Fortunately the Epstein Bill slept in committee, and is still there. The Epstein bill was in our State a very pernicious one and was introduced in Massachusetts and in one other State, in which it failed. I feel that we were fortunate this year in getting a little breathing spell but I feel that before the next session of the national legislature we shall all have to become personally and co-operatively active in our op-

position to that piece of legislation which has in one form or another been before the medical profession insidiously in one place and then in another and now out in the open and we shall have to be very much alive before the organization of the next national legislature in order to prevent the attachment of this particular type of legislation to unemployment insurance legislation.

It is exceedingly important that every doctor should study these things out for himself. But it is even more important that every doctor should appreciate his potentiality as a citizen and as an informed citizen he must accept his responsibility to tell all of the people with whom he comes in contact the real truth about these matters. The people must be educated. The people will be sympathetic if they know anything about it. The great trouble with the medical profession is that they haven't known anything about it they haven't paid any attention to it at all. They are interested in scientific medicine and aside from that, I do not think that they read their medical journals very much. They read just the things that they are interested in if they open the journals at all. They don't even go to society meetings except for interesting programs.

When the question of economics comes up if they know about it to advance there will be a corporal's guard in attendance. Really they are not interested in anything but scientific medicine.

That gentlemen should be a thing of the past. Medicine is changing very much.

The whole scheme of the practice of medicine will be changed in the future and if the medical profession doesn't realize its economic problem it will soon be facing economic slavery.

MISCELLANY

ANNOUNCEMENT

The Hitchcock Clinic, Hanover New Hampshire announces the association of Dr. M. Dawson Tysoo

RECENT DEATH

MITCHELL—ABRAHAM WHITTEMORE MITCHELL, M.D., of Epping New Hampshire died at the Elliott Hospital, Manchester July 31 1885 following an appendectomy. He was born in 1837. He graduated from the New York University Medical College in 1857. He began practice in Epping in 1852 and was the second oldest ex-president of the New Hampshire Medical Society and a Fellow of the American Medical Association. He was a thirty-second degree Mason and had served in the New Hampshire Legislature in 1897 and 1899.

Dr. Mitchell is survived by three children. His wife died a few months ago while on a trip South.

CASE 21331

PRESENTATION OF CASE

A fifty-three year old American housewife entered complaining of shortness of breath of two weeks' duration

One year before entry she began to feel tired and weak. She suffered from shortness of breath at intervals especially upon moderate exertion. Her physician put her on digitalis which he increased in amount as her symptoms increased in severity. She lost about forty pounds in weight during the next six months. A few months after the onset her urine began to have a disagreeable odor but this passed off shortly. A few months later her urine was thick and cloudy on one occasion. Three weeks before admission her weakness and shortness of breath increased. She became dizzy on one occasion and had nausea and vomiting. She stopped her medication and since then the vomiting had not recurred. She had had two attacks of nocturnal dyspnea. During the past two weeks she was bedridden and had shortness of breath at all times except when sitting up. She soon began to have a dry cough. There was no history of edema. During this illness she had many severe headaches behind her left eye. She had nocturia twice a night.

The family, marital and past histories are non-contributory. She had had twelve pregnancies. Nine children were living and well, two died in infancy, and there was one miscarriage. The menopause occurred five years before admission.

Physical examination showed a well-developed and nourished woman in a semi-reclining position breathing very rapidly and with much effort. Her skin was flushed and slightly blue, her lips and fingers cyanotic. Her breath was not urinous. Her hands and feet were cold and clammy. The right fundus showed blurring of the disc margins. The left, however, was clear. In both there was marked narrowing and tortuosity of the arterioles with many small irregular hemorrhages and yellowish exudate. The veins were dilated. Scattered throughout both lungs most numerous at the bases, were many

moist râles. There were signs of fluid at both bases. The heart was slightly enlarged, the left border of dullness being 9 centimeters to the left of the midsternal line, 3 centimeters to the right. The midclavicular line was 8 centimeters from the midsternal line. The sounds were forceful and the rhythm regular. The blood pressure was 210/120 with pulsus alternans between 210 and 190 millimeters. The abdomen was slightly distended. The liver edge was felt five fingerbreadths below the costal margin. It was smooth and slightly tender. The spleen was felt three fingerbreadths below the costal margin and was slightly firm and non-tender. There was slight pitting edema of both legs and very slight edema of the sacrum.

The temperature was 98°, the pulse 102. The respirations were 20.

The urine was cloudy and had a specific gravity of 1.012 to 1.014, a slight trace to a huge trace of albumin, and an occasional white blood cell. Examination of the blood showed a red cell count of 7,800,000, with a hemoglobin of 95 per cent. The white cell count was 14,300, 90 per cent polymorphonuclears. The nonprotein nitrogen of the blood was 77 milligrams. A Hinton test was negative. The oxygen capacity of the blood was 29.6 volumes per cent. The volume of the cells was 66.7 per cent. The volume index was 1.05, the color index 0.99. The stools were negative. An electrocardiogram showed normal rhythm, rate 105, slight left axis deviation, prominent S₂, inverted T₁ and T₂, low upright T₃, inverted P₃ and absent Q₄. The serum protein was 5 per cent.

X-ray examination of the chest showed some fluid in both lower lung fields which prevented demonstration of the exact position of the diaphragm. The heart was slightly enlarged.

The red cell count remained elevated. She was venesected several times with marked relief of her dyspnea. On the tenth day she was started on phenylhydrazine which was given for ten days, a grain and a half each day. She developed a carbuncle on her left buttock which was poulticed. On the fourteenth day she suddenly developed what was called acute pulmonary edema. Her blood pressure was 270/170. A venesection of 500 cubic centimeters was done and she was put into an oxygen tent. She felt well following this. A week later the abscesses of the left buttock were incised and drained. Approximately one month after admission she began to complain of severe left upper quadrant pain. Her temperature rose to 103°. There were tenderness and spasm in the left upper quadrant. A friction rub was heard over her spleen and in the left lower chest posteriorly. A rectal examination at this time was negative. Her red blood cell count had by this time decreased to 3,500,000 and her white cell count had risen to approximately 30,000, 90 per

cent polymorphonuclears. She continued to do poorly; the temperature remained elevated, the abdominal pain did not abate, and she died approximately five weeks after admission and nine days after the onset of the abdominal pain.

DIFFERENTIAL DIAGNOSIS

Dr. CHESTER S. KEEFER.* As one reads the story of this patient's illness it seems clear that the main diagnostic problem is the interpretation of the episode that began nine days before death. Briefly, we have a woman who had the symptoms of heart failure which were progressive over one year. This was characterized by exertional paroxysmal and continuous dyspnea and orthopnea, without conspicuous peripheral edema. In addition there had been loss of weight, unilateral postorbital headaches and nocturia. The dizziness, nausea and vomiting apparently followed digitalis therapy since they disappeared following the discontinuance of the drug.

The physical examination revealed a woman in considerable distress with dyspnea and orthopnea, cyanosis, hypertension with pulsus alternans, pulmonary congestion, bilateral hydrothorax, cardiac enlargement, an enlarged liver and spleen, and edema over the sacrum. The changes in the ocular fundi were consistent with a vascular retinitis, but in addition there was haziness of the right disc and engorgement of the veins.

The laboratory examinations revealed polycythemia and a slight leucocytosis, moderate nitrogen retention, albuminuria with a reduced specific gravity. The electrocardiographic tracing was consistent with that found in patients with hypertension and sclerosis of the coronary vessels supplying the anterior wall of the left ventricle with myocardial fibrosis.

From these findings, one would not hesitate to make the diagnosis of vascular disease with hypertension, cardiac insufficiency and polycythemia vera.

The course of the illness in the hospital was punctuated by three episodes: (1) the development of acute pulmonary edema which was a sign of progressive heart failure, (2) the appearance of a furuncle on the buttock, and (3) the attack of abdominal pain, localized in the left upper quadrant and accompanied by tenderness and spasm of the abdominal wall, a friction rub over the spleen and in the lower part of the chest, fever and leucocytosis.

When a patient with heart failure complains of pain in the left upper quadrant one naturally thinks of infarction of either the lung or spleen. In this patient, the presence of a friction rub over the spleen, without cough or expectoration, would lead one to suspect that the infarct was in the spleen.

When a patient with polycythemia complains

of acute abdominal pain one entertains the possibility of either a vascular accident or a perforated gastric or duodenal ulcer. Both conditions are fairly common in this disorder. Of the vascular accidents, one has portal, splenic or mesenteric thrombosis, or thrombotic occlusion of one of the branches of the coronary or splenic arteries. The latter is more common. From the story and course of events it would not be possible to make a diagnosis of occlusion of one of the large veins mentioned. However, there is no serious objection to the diagnosis of infarction of the spleen. If this line of reasoning is correct it is necessary then to explain how this infarction arose. Two possibilities I have mentioned already, but there is a third, namely, a septic infarction of the spleen following the infection of the buttock. This is suggested by the presence of high fever and leucocytosis, accompanying the signs of splenic infarction. It is not absolutely diagnostic, however, since bland infarctions of organs such as the kidney or spleen may be accompanied by fever and leucocytosis. As a rule, however, the duration is somewhat shorter than nine days unless there is a superimposed infection.

The leucocytosis might be explained on a basis of the phenylhydrazine therapy. Generally speaking, the increased leucocytosis produced by phenylhydrazine does not persist more than ten days after the drug has been discontinued, so that it seems unlikely that the phenylhydrazine treatment can account for the leucocytosis in this case, since it was discontinued approximately ten days before the onset of the pain in the abdomen.

There remains for discussion the question of the relation, if any, between the polycythemia and the cardiac insufficiency. Polycythemia is seen in certain types of congenital heart disease, and in the heart failure resulting from chronic pulmonary fibrosis or kyphoscoliosis. In this particular case these conditions can be excluded at once. There are a few patients, however, with polycythemia and hypertension in whom the symptoms and signs of the disease may be predominantly those of the hypertension. In these cases it is necessary to exclude instances of suprarenal and hypophyseal tumors. Once this has been done there remains a group of patients with hypertension and polycythemia in whom the precise relationship between the two conditions is difficult to define. As a rule the spleen is not enlarged and the blood pressure may be lowered following the reduction of the red blood cells. In the present case I am unable to see how the cardiac insufficiency and the polycythemia are related to a common cause unless one assumes that the generalized vascular disease which is so common in these cases is the primary lesion and the polycythemia is secondary to diffuse vascular lesions of the bone marrow which produce anemia and a stimulation of red cell production.

*Associate Physician, Thorndike Laboratory of the Boston City Hospital.

X-RAY INTERPRETATION

DR GEORGE W HOLMES The x-ray film shows a rather characteristic picture of a somewhat dilated heart with passive congestion in both lungs. The condition in the lungs obscures the outline of the heart to such an extent that one would not be able to say whether this was a dilated hypertensive heart or some other heart lesion. There is also evidence of fluid at the bases.

CLINICAL DISCUSSION

DR WILLIAM D SMITH This case has been discussed so adequately that there isn't much to say. The consensus of the service was that she had polycythemia vera and then the question came up whether the hypertension might be secondary to the polycythemia.

DR GRANTLEY W TAYLOR We saw this patient on the surgical service because of her carbuncles, which we treated. Then this final complication developed. We found very little else but what is stated here, tenderness, spasm, high white cell count, elevation of temperature and the complaint of a good deal of pain on the patient's part. The onset was very abrupt so much so that although we considered the possibility of metastatic abscess of the spleen we were inclined a little more to consider that it was a splenic thrombosis secondary to polycythemia rather than bacterial infection. The question arose whether exploration was called for if so what we would attempt, and there again we did not have a very definite plan of campaign unless we found an abscess. We thought abscess was an extremely unlikely possibility. She was transferred back to the medical service and I do not believe we saw her again after that original episode.

DR FRANCIS T HUNTER I want to call your attention to the fact that we are having, with Dr Holmes' assistance, rather good luck with radiation of patients with polycythemia vera. My experience with phenylhydrazine has been very unpleasant because in order to get results you have to push up the dose almost to the point of nausea. The two cases we have radiated have had counts of eight or nine million. We gave them spray radiation, a rather enormous dose for three weeks and after months of rest when the count did not change we repeated. These two patients—one two years now the other eighteen months—have had no change in their red count—from four to four and a half million. I think this method of treatment offers something to these people that we have not been able to give previously.

A PHYSICIAN What white cell counts did your cases have?

DR HUNTER In the neighborhood of fourteen, fifteen or eighteen thousand. They came down to six thousand.

A PHYSICIAN Did any of the cases have a leukemic blood picture?

DR HUNTER No, the leukemias have not done nearly so well.

CLINICAL DIAGNOSES

Polycythemia
Splenic thrombosis
Carbuncles
Mesenteric thrombosis?
Pylephlebitis?
Cardiovascular renal disease

DR CHESTER S KEEFER'S DIAGNOSES

Hypertension with arteriolar sclerosis
Coronary arteriosclerosis with myocardial fibrosis
Cardiac insufficiency
Benign nephrosclerosis
Polycythemia vera with enlargement of the liver and spleen
Splenic infarction with perisplenitis due to thrombotic occlusion of a branch of the splenic artery
Splenic abscess?

ANATOMIC DIAGNOSES

Polycythemia
Splenomegaly
Septic infarcts of the spleen
Thrombosis of the splenic artery
Pulmonary abscesses, multiple
Pleuritis, acute fibrinous
Carbuncles of left buttock
Cardiac hypertrophy, hypertensive type
Benign nephrosclerosis
Leiomyoma of the esophagus

PATHOLOGIC DISCUSSION

DR TRACY B MALLORY The autopsy was characterized by a single outstanding feature, a very large spleen weighing 750 grams. It showed very nearly complete infarction although the infarcts were multiple, so numerous as to be contiguous, with practically no normal tissue between them. We found the splenic artery completely thrombosed, a part of the thrombus evidently being quite an old affair since it was fibrous and in places calcified. Then there was a fresh, completely occluding thrombus which I assume was terminal and which accounted for the last episode. In all probability she had had at least one preceding attack of splenic thrombosis, a matter of months or years before. The infarcts in the spleen had not as yet broken down but the amount of leukocytic infiltration in some places suggested that there was probably a septic element to them, but there certainly was nothing that one could call an abscess and nothing that could have been surgically drained. She did have definite abscesses elsewhere most noticeably in the lungs, which were

peppered with small ones varying from a millimeter up to a centimeter and a half in size. One or two of these had evidently in the last few hours of life broken through into the pleural cavities. An acute fibrinous pleuritis presented in both pleural cavities but was as yet not very extensive.

The stomach was very carefully examined for evidence of present or past ulcer and no acute erosions and no scars of any sort were found. We did find incidentally—nothing of any clinical importance to the case but rather unusual—a leiomyoma of the lower end of the esophagus a small one about 2 centimeters in diameter.

The heart weighed 350 grams which is slight hypertrophy for a woman. The coronary arteries were capacious and practically free from atheroma. The kidneys were definitely small weighing only 175 grams, showing as Dr. Keefer predicted a fairly marked degree of benign nephrosclerosis.

The sepsis had made its way to the head also and acute suppurative sinusitis was found in the left frontal sinus and in the ethmoid with a somewhat more questionable lesion in the right frontal.

Microscopically the feature of greatest interest is the bone marrow which showed a very marked degree of hyperplasia not only in the usual blood forming areas, that is the vertebrae ribs and various flat bones, but also in the portions of the marrow usually composed only of fat tissue, for instance in the middle of the femur where the marrow was deep red in gross and microscopically the fat cells are replaced by active hematopoiesis. The excessive blood formation is not limited however to the red cell series as it would be in pernicious anemia for instance. Red cells, white cells and megakaryocytes seem to be present in normal proportions but in greatly increased numbers. Moreover, the differentiation of all the cells seems to be going through to conclusion. One has no striking predominance of immature cells, such as one finds in either pernicious anemia or leukemia. The vessels of the marrow with ordinary stains show nothing abnormal. It is possible that with special stains we might bring out some arterial thickening but I have not been able to demonstrate it in our ordinary sections.

DR. HOLMES: This film was taken two months before. It is quite possible that the abscesses that you found were not present at the time.

DR. MALLORY: No, I think the abscesses developed only in the last week or two.

DR. ARLE V. BOCK: I should like to ask Dr. Keefer to explain the electrocardiographic findings in view of your findings.

DR. KEEFER: I am not able to do that. Have you any explanation?

DR. BOCK: No. I cannot explain any of

them. I think that very often they are too finely drawn.

DR. KEEFER: The only reason I mentioned it is that in our experience within the last year or two the prediction of the location of a myocardial lesion from the type of electrocardiographic change has been rather accurate and I think it is a more than academic question. As you follow a series of patients who have coronary occlusion and show electrocardiographic signs through the wards you find that a high proportion of those who do well for a long period of time have posterior infarctions where as those who have anterior infarctions do very poorly.

CASE 21332

PRESENTATION OF CASE

First Admission. A sixteen year old native schoolboy entered complaining of diarrhea.

Approximately one year before admission he noticed the onset of more frequent bowel movements and a change from the normal character to that of a watery secretion. At this time there was no blood, mucus or tarry stools and no abdominal pain. Two months later because of the persistence of these symptoms he visited a physician who gave him milk of bismuth and pepsin. This however, gave no relief. He then began to lose his appetite tire more easily and for the first time noticed that his skin was gradually becoming pale yellow in color. These symptoms gradually progressed until he was having six to eight bowel movements every day and about three months before entry he noticed for the first time a small quantity of dark red blood in each movement. He visited the Out Patient Department five weeks before entry where his treatment consisted of bismuth powders, soft diet, liver soup, cod liver oil, tomato juice and red bone marrow. During the month before admission his stools became slightly less watery and very often contained no blood. He felt that he had improved generally had gained a little weight and had more ambition. He had not been confined to bed and had been attending school fairly regularly. His weight did not change. He recently had a little dyspnea on exertion but no other symptoms.

His father and mother were both living and well. Two sisters were living and well. There was no familial history of tuberculosis or colitis.

His past history was negative except for an attack of painful but not swollen joints two years before entry requiring bedrest for a week.

Physical examination showed a well-developed and well nourished boy. The skin and mucous membranes were pale. The teeth were normal. The lungs were clear. The heart was slightly enlarged to percussion and palpation. At the

apex there was a blowing systolic and a low pitched rumbling diastolic murmur. The blood pressure was 130/70.

The temperature was 99.6°, the pulse 120. The respirations were 25.

Examination of the urine was negative. Examination of the blood showed a red cell count of 4,800,000, with a hemoglobin of 50 per cent. The white cell count was 14,200, 73 per cent polymorphonuclears. There was marked achromia. Five stool examinations were negative except for slight watery consistency. The guaiacs were negative for the first week. A Hinton test was negative. The serum protein was 6.5 per cent. A dysentery agglutination test was negative. Tuberculin tests up to 1:1000 were negative. Gastric analysis showed a normal amount of free acid. The guaiac was negative.

A barium enema showed complete lack of haustral markings. The rectum was not definitely diminished in size. The cecum showed no spasm. There were no haustral markings and the size of the cecum was that of the descending colon. The terminal ileum showed slight variation from normal. Examination of the chest was essentially negative.

He did fairly well for the first week. He showed no evidence of blood in his stools. His temperature chart was flat. About ten days after admission his stools became more watery and showed definite blood. The guaiacs in his stools remained positive for the next two weeks, although he felt much better. Approximately one month after admission he was discharged improved. He was put on a low residue diet, given one yeast cake three times a day, one half a pound of domestic liver extract daily, and iron and bismuth subcarbonate p r n.

Second Admission, six days later

When he was discharged he had been having only four to six stools daily. After he was home for two days he began to vomit and soon his diarrhea increased markedly, requiring bowel movements every one or two hours at night and about every three hours during the day. Associated with this diarrhea was cramp-like abdominal pain. He lost his appetite and felt very weak.

Physical examination was the same as on his previous admission, except for slight tenderness over the course of the colon, especially in the left lower quadrant.

The temperature was 100.3°, the pulse 103. The respirations were 20.

Examination of his blood showed a red cell count of 7,450,000, with a hemoglobin of 95 per cent. The white cell count was 6,800, 64 per cent polymorphonuclears. The stools were watery, green brown in color and had a four plus guaiac.

Two days after admission an ileostomy and appendectomy were performed. For the fol-

lowing few days the chart was satisfactory and the ileostomy was working well. One week after operation he began to vomit a great deal and became slightly distended. The ileostomy was still draining. Aspiration of the stomach yielded sixty ounces of upper intestinal contents containing occult blood. The abdomen became more distended. He became irrational. His temperature rose to 107.5°, the pulse to 170 and the respirations to 30. He died nine days after operation.

DIFFERENTIAL DIAGNOSIS

DR WILLIAM B BREED. There is very little in the present illness in the way of a differential diagnosis. It would seem that he was well on his way toward idiopathic ulcerative colitis. I think that tuberculous colitis in a child like this is not to be considered very seriously. Of course, one must consider the various parasites. I assume that later in the history we shall investigate the question of parasites, also the question of tuberculin tests, etc. Probably x-rays of the chest and stool examinations follow down the diagnosis of tuberculosis and parasitic disease, but offhand I should think that such efforts were fruitless.

"His past history was negative except for an attack of painful but not swollen joints." That is of interest because of the question of possible rheumatic fever—merely as an incidental process, however, because this story of colitis is not often associated with rheumatic fever in children. He may have had rheumatic fever. We should like to know what the examination of his heart was prior to his entry and whether any doctor had ever noted any evidence of rheumatic heart disease. There is some evidence here to indicate that this boy has rheumatic heart disease and in view of the enlargement of the heart I think it may turn out that he has. On the other hand, if he had only a severe degree of anemia we might get these findings through the stethoscope. He might have the systolic murmur of course, and one does rarely get a diastolic murmur in severe anemia which clears up with the improvement of the anemia. Our experience in the House of the Good Samaritan is that very many times we get a rumbling diastolic murmur during the acute stage of the disease, even in the presence of true rheumatic heart disease, and later on find that it disappears. Frequently in such a case no stenosis can be demonstrated at autopsy. So, in view of the enlargement I think we have to say he has mild rheumatic heart disease, but I am not prepared to say he will show stenosis of the mitral valve. We get very meek about this question of diastolic murmurs because we have been tripped up too many times in making the diagnosis of mitral stenosis on the basis of a diastolic murmur at the apex and finding later no real stenosis of the valve.

He has hypochromic anemia, secondary in

type, with a rather surprisingly high red cell count. I should like to have that checked because one would rather expect with a hemoglobin of 50 not quite such a high red count even though it is a hypochromic anemia.

DR. BENJAMIN CASTLEMAN The hemoglobin was repeated a week later and was 60 per cent. Two weeks later the red cell count was 5 400 000 with a hemoglobin of 60 per cent.

DR. BREED "Tuberculin tests up to 1 1000 were negative." That practically rules out tuberculosis, 1 1000 is a strong dilution.

It does not say anything about examination of the stools and culture for amebae.

DR. CASTLEMAN They were done and were negative.

DR. BREED I think this is a perfectly good picture for ulcerative colitis.

DR. CASTLEMAN I might say, Dr. Breed that x-ray examination of the heart showed no enlargement.

DR. BREED And no mitral shape, I take it.

DR. CASTLEMAN No.

DR. BREED This diastolic murmur might be a red herring, also the question of enlargement. I am not sure he has rheumatic heart disease at all.

Apparently then, on the basis of how he was treated, the hospital diagnosis was ulcerative colitis. Of course, the hospital may be wrong.

He came in again after six days. Something must have come up of an acute nature that sent him back into the hospital.

I have not read the history but I imagine he got so much worse that they operated on him. That brings up the question of why they did not operate on him sooner. He was pretty well during his first stay. I think the one temptation with these people is to let them go until they get in such poor condition they are had risks.

There is remarkably successful treatment of anemia here! His hemoglobin which was 50 per cent is now up to 95 per cent, unless he was dehydrated. I think the smear would be of some value.

DR. CASTLEMAN He was very ill and dehydrated at the time.

DR. BREED I do not see how that would make the red cells appear normal as quickly as this. One of these examinations must be faulty.

DR. CASTLEMAN A week before he left the hospital the red count was 5 4 and the hemoglobin 60. No smear is recorded.

DR. BREED I see here that they did operate on him.

Did they examine the heart at this admission?

DR. CASTLEMAN The heart was normal in size. There was a blowing systolic murmur at the apex, transmitted to the axilla.

DR. BREED Any diastolic murmur?

DR. CASTLEMAN A₂ was equal to P₂. There was no diastolic murmur heard.

DR. BREED I do not know whether we can find the exact cause of death. Intestinal obstruction is not indicated. We know that the stomach contents showed upper intestinal fluid. He may have had ileus from toxemia. I think he just died from colitis and operation and I think it is futile to inquire into the exact and distinct cause of death. I should doubt if you find real intestinal obstruction. I am going to say that he did not have rheumatic heart disease. I am assuming that he did not have amebic dysentery and that he died of ulcerative colitis. It is what one would expect in a young person because the younger they are the more severe they are as a rule.

A PHYSICIAN Was a proctoscopic examination done?

DR. BREED There is no record of it.

A PHYSICIAN How about the blood picture?

DR. BREED I am assuming that he had a secondary anemia due to blood loss and toxemia.

A PHYSICIAN Do you think it was primary blood disease? I am wondering how much dependence you can put on the record as to the blood picture.

DR. BREED I am not willing to put very much on it. It contradicts itself. I am going to leave the blood picture out. I think he had secondary anemia. I will take the first report rather than the second one.

Of course, the outlook in a person of this age is very gloomy with or without operation and one cannot look back and say that if he had been operated on earlier he would have survived. But, as I said before, people often hesitate too long in operating on ulcerative colitis. Naturally, it is well to hesitate for a certain length of time to be sure of the diagnosis, because it is very disconcerting to operate by mistake on a case of amebic dysentery or the like.

CLINICAL DIAGNOSES

Ulcerative colitis
Acute appendicitis
Intestinal obstruction

DR. WILLIAM B. BREED'S DIAGNOSES

Idiopathic ulcerative colitis
Hypochromic secondary anemia.
Ileus?

ANATOMIO DIAGNOSES

Chronic ulcerative colitis
Peritonitis, generalized, acute.
Appendiceal abscess, retroperitoneal, localized
Intestinal obstruction ileum
Operative wounds Ileostomy appendectomy, jejunostomy
Hydronephrosis, right.
Pulmonary congestion.
Hydrothorax, left.

PATHOLOGIC DISCUSSION

DR CASTLEMAN He had no rheumatic heart disease. The heart was small and showed no valvular lesions. He was very pale and emaciated, and weighed only 85 pounds. On opening the abdominal cavity it was found filled with slightly turbid hemorrhagic fluid. The surfaces of the intestine were all covered with a fibrinous exudate. There was also a moderate degree of intestinal obstruction in the ileum, produced by a small kink due to adhesions of fibrinous bands. The colon throughout, beginning at the cecum and extending down to the anus, showed numerous ulcerations and in between the ulcerations there were small areas of mucosa that appeared raised, the so-called pseudopolyps, but no true adenomatous polyps at all and no evidence of carcinoma. There were no perforations or fistulae. He had some congestion in his lungs and a little fluid in the pleural cavities but no evidence of pneumonia. The bone marrow was tremendously hyperplastic, a finding which would go well with the hypochromic anemia.

DR BREED What sort of peritonitis was it?

DR CASTLEMAN *Bacillus coli*.

A PHYSICIAN How often do these ulcerative colitis cases perforate? As often as amebae?

DR CASTLEMAN There is a type of acute ulcerative colitis in which the symptoms are only of two or three weeks' duration before death ensues. This type is much more prone to perforate than the chronic type with remissions. The chronic type on the other hand is more prone to develop strictures and polyps. The Mayo Clinic has recently reviewed 800 cases and found that 2½ per cent of them developed adenocarcinoma¹. Ten per cent developed true adenomatous polyps, not the pseudopolyps that you ordinarily see, true polyps. We have had only one case of carcinoma associated with chronic ulcerative colitis². In this case there were multiple carcinomata, a fact that suggests that the tumor arose on a previous irritative focus.

A PHYSICIAN How do you account for the systolic murmur?

DR BREED I think on the basis of anemia, even the diastolic murmur.

A PHYSICIAN His diastolic murmur disappeared but the systolic did not.

DR BREED With nothing else to back up the diagnosis of heart disease a systolic murmur can be thrown out. That is, with no enlargement and no evidence of any heart disease other than the murmur you had better disregard it.

I wonder what the joint pains were two years before. He might have had rheumatic fever. Some have rheumatic fever even at this age without heart disease, but very few, of course, escape without cardiac involvement.

A PHYSICIAN Would a proctoscopic examination have cleared up this picture? If there was ulcerative colitis you should see the ulcers quite easily.

DR BREED They felt pretty certain that it was true ulcerative colitis and did not consider anything else after the negative tuberculin test. They did not consider amebic dysentery very seriously. Some people say they can tell the difference between ulcerative colitis and amebic colitis by proctoscopic examination but it is very difficult in some cases. I know of two that were wrongly diagnosed by proctoscopy, amebic dysentery was called ulcerative colitis.

A PHYSICIAN Do you ever have diarrhea and constipation in idiopathic colitis?

DR BREED They have spontaneous remissions and during the remission they may be constipated.

A PHYSICIAN Supposing that he had not been secondarily infected, what would be the chances of cure?

DR BREED I think not very good because sometimes even with an ileostomy they will go on and have colitis. All you do is short circuit the bowel stream from the colon and let it rest. They do not attempt to close the ileostomy any more. Do you know of any cases where the circuit has been reestablished and a cure obtained, Dr Castleman?

DR CASTLEMAN I do not think that there have been any in this hospital.

'CONTINUING MEDICAL EDUCATION'

UNDER this suggestive caption*, the Vice-President in Charge of University Relations, University of Michigan describes Michigan's Postgraduate Program for keeping practitioners up to date in their knowledge of the science and of the art of medicine. The problem is stated in a quotation from Osler "The family doctor, the essential factor in the battle, should be carefully nurtured by our schools and carefully guarded by the public." The responsibility of the public is generally lost sight of, but the participation of the schools has always been regarded as necessary. It is here that the teachers must chiefly be sought and found that the form and degree of participation have varied in the numerous experiments made in many states. Osler was writing on the "Educational Value of Medical Societies", and it is to the state society that the general practitioner must look for the

chief means for solution of the problem, with which he is by himself helpless to deal.

All of these experiments in "continuing medical education" are worthy of close scrutiny and study, for the physician should be a student all his life, but among the growing group the Michigan experiment especially deserves attention. The details need not be specified now naturally they might be different in Michigan with a state university from what would be appropriate in Massachusetts.

The efforts of the Massachusetts Medical Society have met with encouraging response, but the opportunities have been merely touched. The bands of those responsible for the rather modest program should be upheld and they should be encouraged by suggestion and helpful criticism.

The possible results of a wise program carried out over a period of years are very great. Already as Dr. Bruce says of Michigan "There has been a decided improvement in the morale of the medical profession of the state, and evidence of a helpful coöperative attitude of one physician to another stimulated by the class room contacts. In addition there has developed a teaching talent in many well informed practitioners and specialists which hitherto has not had opportunity to express itself. But possibly more important than all, the standards of social responsibility of the profession have gone forward, as well as those of medical practice, with the evidence of a renewed confidence on the part of the people."

If these results may reasonably be expected, the movement deserves the support of every member of the medical profession and especially of every member of the state society.

INDUSTRIAL DISEASE REFEREES

UNDER House Bill 2147, enacted recently, the text of which appears on page 338 of this issue, provision is made for the selection, by the Industrial Accident Board, of impartial physicians who may examine a claimant for compensation, for "injury due to an industrial disease", and "may cause to be made an inspection of the place or places of employment."

The selection of these referees is to be made from a list of registered physicians prepared by the Board of Registration in Medicine. Whether this list shall be the entire list of registered practicing physicians, or a list of those considered suitable by the Registration Board does not appear. The last paragraph of the act provides for a revision of the list on the request of the Industrial Accident Board. Whether this in turn means a revision to delete those who no longer practice and include new registrants, also does not appear. The assumption that discretion lies with the registration

*Continuing Medical Education: James D. Bruce, M.D. The American Scholar Vol. 4, No. 2 Spring 1935

board may be the intention of the framers of the bill. If indicated, the reviewing board may refer the matter back to the referees for further diagnosis.

One may see that the operation of the provisions of this act may be a reasonable resource for the injured workman, if the service rendered by the Industrial Accident Board, the Board of Registration, the Impartial Referees and the Reviewing Board is free from political influences.

Under the operation of this act, if the injured workman, the doctors and the insurance companies all find that the results are satisfactory, it may prove to be a step in the right direction. The results of the operation of this act will be watched with interest.

THE RESPONSIBILITY OF OWNERS OF DOGS

THE Massachusetts Department of Public Health is placing on owners of dogs the responsibility of a large proportion of the almost three hundred cases of rabies in this state during the past year.

About one thousand persons who were bitten by or exposed to these dogs or bitten by stray dogs have had to take antirabic treatment. One untreated child bitten by a stray dog died of rabies.

Rabies is on the increase, with the spread to several sections of the state from the metropolitan area.

Here is a public health opportunity in which doctors may participate by telling the owners of dogs, among their patients, to have the animals immunized. Veterinarians will give the required treatment. Rabies is one of the most horrible diseases, but fortunately is largely preventable.

MASSACHUSETTS LEGISLATIVE NOTE

House 2147 as enacted

AN ACT providing for the reference of certain cases under the Workmen's Compensation Act to industrial disease referees

Chapter one hundred and fifty two of the General Laws is hereby amended by inserting after section nine A as appearing in the Tercentenary Edition the following new section —

SECTION 9 B The board of registration in medicine shall as soon as this section takes effect prepare and transmit to the department a list of registered physicians In the event of any employee or in case of his death his legal representative or dependents making a claim for compensation alleging that his injury is due to an industrial disease, the industrial accident board shall submit the claim to three physicians selected by it from said list, who shall be impartial Such three physicians shall be known as industrial disease referees They may make such examinations of the employee and cause to be made such inspections of the place or places of employment as they deem necessary and shall report their diagnosis to the department. The insurer shall reimburse the department for the fees and other expenses of such referees subject to the approval of the industrial accident board The diagnosis shall be made by a majority vote of the referees and shall be included in the decision of the single member and in the decision of the reviewing board and such diagnosis shall be binding on the parties. The reviewing board if a claim for review is filed may refer the matter back to the industrial disease referees for further diagnosis The board of registration in medicine from time to time may and on request of the industrial accident board shall revise the list of physicians from which industrial referees may be appointed and shall notify the department of such revision

MISCELLANY

APPOINTMENTS AT THE BOSTON UNIVERSITY SCHOOL OF MEDICINE

DR MCKHANN VISITS CHINA

Dr Charles F McKhann Assistant Professor of Pediatrics at the Harvard Medical School has gone to China where he will be Visiting Professor of Pediatrics at the Peking Union Medical College during the first half of the school year 1935 and 1936 He will return to Boston early in March, 1936

CORRESPONDENCE

THE CHANGING ORDER IN MEDICAL CONVENTIONS OR A SUGGESTION FOR THE PROGRAMS OF MEDICAL CONVENTIONS

Editor *New England Journal of Medicine*,

The increasing value of the Scientific Exhibit at the conventions of the American Medical Association has impressed itself upon the attention of every visitor Two features of the Exhibits in recent years have been prominent

(1) The demonstration of new methods of diagnosis and treatment.

(2) The extension of knowledge of modern methods and medical concepts through the personal energy and enthusiasm of individual exhibitors.

The program at large medical conventions has become so extensive and diversified that greater correlation of the didactic portions with the exhibits seems necessary The didactic papers given in various sections would gain tremendously in interest and effectiveness if accompanied in some way by active demonstration of some phase of the subject. The use of moving pictures of slides which can be stopped at any point for elaboration of some point or the answer

board may be the intention of the framers of the bill. If indicated, the reviewing board may refer the matter back to the referees for further diagnosis.

One may see that the operation of the provisions of this act may be a reasonable resource for the injured workman, if the service rendered by the Industrial Accident Board, the Board of Registration, the Impartial Referees and the Reviewing Board is free from political influences.

Under the operation of this act, if the injured workman, the doctors and the insurance companies all find that the results are satisfactory, it may prove to be a step in the right direction. The results of the operation of this act will be watched with interest.

THE RESPONSIBILITY OF OWNERS OF DOGS

NOTICES

REMOVAL

M. L. KRAFT M.D., announces the removal of his office to 93 Washington Avenue Chelsea, Mass.

A VACANCY FOR A PHYSICIAN

An opening for a country practice exists in Massachusetts. Call at the office of the *New England Journal of Medicine*

UNITED STATES CIVIL SERVICE EXAMINATIONS

The United States Civil Service Commission has announced open competitive examinations as follows:
Public Health Specialists

Applications for a number of specialist positions in the U. S. Public Health Service, Treasury Department, must be on file with the U. S. Civil Service Commission, Washington, D. C., not later than September 9, 1935. These positions include several grades of bacteriologist, cytologist, epidemiologist, and mycologist (medical) positions and the position of senior pathologist (medical).

Area Medical Director \$5,600 a Year
Indian Service, Department of the Interior

Applications must be on file with the United States Civil Service Commission at Washington, D. C., not later than August 26, 1935.

The United States Civil Service Commission announces an open competitive examination for the position named above. Vacancies in this position and in positions requiring similar qualifications will be filled from this examination unless it is found in the interest of the service to fill any vacancy by reinstatement, transfer or promotion. The salary named above is subject to a deduction of 3 1/2 per cent toward a retirement annuity and to a further deduction of \$400 for Government quarters when furnished.

REPORT AND NOTICE OF MEETINGS

THE SOUTHEASTERN MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH

The Southeastern Massachusetts Association of Boards of Health held its annual meeting in the Town Hall at Marion on Wednesday, July 31, some sixty persons being in attendance. After a busi-

ness meeting, which included the reading of reports of the secretary and treasurer, the election of officers was in order, resulting in the following list for the coming year:

President, Dr. T. L. Swift; Fulmouth Vice-Presidents, Dr. G. E. Ward, Orleans, and Joseph Christy, Dartmouth; Secretary-Treasurer, George F. Crocker, Marston's Mills; Executive Committee, Dr. R. P. MacKnight, New Bedford; Dr. W. O. Hewitt, Attleboro; and W. F. Delano, Fairhaven.

In a brief address of greetings, Walter K. Perry of the Marion committee sketched the admirable work in health and public sanitation effected by the town. Some forty years ago an improvement association was formed, the first work of which was a campaign against the fly which included the screening of cellars and proper care of manure heaps. Next, work was toward the elimination of the mosquito. In this more than \$45,000 has been expended and the territory covered includes breeding places in neighboring towns. Marion has expended \$165,000 for a sewer system the sewage being pumped to a basin far removed from the shore and there treated so that there is no pollution of coastal waters. The water system which has a longer mileage than the streets since it supplies cottages at the shore cost about \$300,000. Even with these costs the town's indebtedness today is only \$100,000. There are two full-time nurses serving the town.

The speaker for the occasion was Hermann C. Lythgoe, S. B. Director of the Division of Food and Drugs, Massachusetts Department of Public Health, who presented the important points of recent legislation affecting the sale of mixtures containing alcohol or narcotics, the licensing of the manufacture and sale of soft drinks, and the inspection by the local health officers of dairies furnishing milk to towns.

Following the formal meeting the company adjourned to the Old Stone House where a collation was served.

MIDDLESEX SOUTH DISTRICT MEDICAL SOCIETY

The Mid-Summer meeting will be held Wednesday, August 21, 1935. The undersigned will act as host. Among the attractions are the following: An opportunity for an afternoon in Bedford. Any "New Dealers" will be very welcome regardless of their rash ideas but can expect to have some in jections of horse and dog sense and scents.

My unpretentious ranch has been in existence since 1695 and is located on the North Road in Bedford about one mile beyond the centre of the village and four miles north of Lexington.

There is an opportunity for any number to swim in the pool and for a limited number to ride horseback through the woods. They should come

prepared for riding and let the undersigned know their intentions so that plans can be made for suitable mounts. There is unrivaled opportunity for hiking through the primeval woods. There is a suitable field for ball games and an opportunity for quoits and archery.

Arrangements can be made for any number to play golf at the Paul Revere Golf Club which is but a short distance from the Farm. It is quite essential to notify the undersigned in advance as to the number who would care to spend the afternoon golfing.

There will be a clambake on one of the hills at about 12:30 or 1 o'clock.

When arriving in Bedford you continue north on Route No. 4, the main road going toward the mountains, for about one mile. When coming from the south or east of Lexington, you turn to the right at the Battle Green on Bedford Street and continue straight to the centre of Bedford. If coming from the northeast, you follow Route 62 directly to Bedford Centre. If coming from the north or west you can follow Route No. 4 from Chelmsford Centre directly to the Farm or Route No. 2 or No. 2A to Concord and then No. 62 to Bedford.

If Wednesday, August 21 should prove to be rainy or unpleasant, the meeting will be postponed until the following Wednesday.

In order that the necessary provisions may be made, please notify the undersigned promptly.

G. V. BUEHLER

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING MONDAY, AUGUST 19, 1935

Wednesday, August 21—

12 M. Clinico-Pathological Conference Children's Hospital.

Saturday, August 24—

*10-12 Staff rounds at the Peter Bent Brigham Hospital.

*Open to the medical profession.

†Open to Fellows of the Massachusetts Medical Society.

August 29 - September 5—Latin American Congress of Physical Therapy, X-Ray and Radium. For information address Dr. Madge C. L. McGuinness, 1211 Madison Avenue, New York City.

September 5, 6, 7—American Congress of Physical Therapy will meet at the Hotel Kansas City, Kansas City, Missouri. Program and circular of information may be secured by addressing American Congress of Physical Therapy, 30 North Michigan Avenue, Chicago, Illinois.

September 17, 18, 19—Eleventh Clinical Congress of the Connecticut State Medical Society. For details address Dr. Creighton Barker, 129 Whitney Avenue, New Haven, Conn.

October 7-10—American Public Health Association will meet in Milwaukee, Wisconsin. For information address the American Public Health Association, 50 West 50th Street, New York City.

October 21 - November 2—1935 Graduate Fortnight of the New York Academy of Medicine. See page 898, issue of May 9.

October 28 - November 1—The Twenty-Fifth Clinical Congress of the American College of Surgeons. See page 1065, issue of May 30.

BOOK REVIEWS

Diseases of the Skin Richard L. Sutton and Richard L. Sutton Jr Ninth edition 1433 pp St. Louis The C. V. Mosby Company \$12.50

This standard textbook of dermatology has been thoroughly revised and brought up to date. In this edition the senior Dr. Sutton has included his son as co-author although the latter has collaborated with him in previous editions. The literature since the last edition has been completely covered and twenty-eight new dermatological conditions have been included in this edition. The 1310 illustrations cover the specialty extremely well and add greatly in diagnosis. It is one of the best pictorial exhibits in any textbook on cutaneous diseases. Included also are many photomicrographs well chosen and excellent in quality.

The section on syphilis has been revised and expanded to eighty-seven pages. The text is illustrated by the large number of excellent photographs and there is an excellent bibliography.

In general there are many references to all conditions for the student seeking further information. Individual methods of treatment are stressed although reference is made to other therapeutic methods. This book can be recommended to student and practitioner alike as a thoroughly excellent source of information on cutaneous disease.

Maladies infectieuses A Lemierre 406 pp Paris Masson et Cie 60 fr

This book which strikingly reminds one of The Clinics of North America, is an excellent presentation of a wide variety of disorders of infectious origin. Since the work is essentially a monograph on nature the diseases discussed are those usually not treated at any great length in the usual text on infectious diseases. For example instances of benign tetanus undulant fever acute infections nephritis typhus the various forms of meningitis and amebic abscess are among those described and discussed. Each case is taken up at length and its salient features presented in such fashion that there should be no question as to the possibility of its retention. Although exception may perhaps be taken to the title "diphtheritic nephritis" heading the chapter dealing with this particular complication of diphtheria this minor point should be disregarded in evaluating the work as a whole. It is recommended not only to physicians and students especially interested in the infectious diseases but to the general practitioner as well.

Sedgwick's Principles of Sanitary Science and Public Health Rewritten and enlarged by Samuel C Prescott and Murray P Horwood. 654 pp New York The Macmillan Company \$4 25

A generation ago and more Professor Sedgwick of the Massachusetts Institute of Technology was an inspiring force in awakening the public to a realization of the economic importance of the prevention of disease. His influence was chiefly due to his attractive and persuasive personality, but to some extent also to his book published in 1901, *The Principles of Sanitary Science and Public Health*.

This book long since out of date and undependable, Professors Prescott and Horwood have undertaken to rewrite to serve primarily as a textbook for "students in science or engineering interested in sanitary science and public health," preserving Professor Sedgwick's form of presentation and changing the substance as has appeared necessary to them in the light of better knowledge and wider practical experience.

The present edition has 600 pages. The subjects treated are presented in twenty-eight chapters, beginning with a consideration of "Health, Old Age and Disease," the Etiology or Causes of Disease "Ancient and Modern Theories," "The Rise and Influence of Bacteriology," and "Sanitary Aspects of the Struggle for Existence, Factors Affecting Survival," and ending with a chapter on "Organization for Public Health Administration in the United States."

Among the other chapter headings are "Refuse Collection and Disposal," "The Protection and Purification of Public Water Supplies," "Milk Supplies and the Public Health."

Where the phenomena of life are considered as in the introductory chapters and that relating to "Nutrition on the Public Health," a professorial physician who has been bedeviled by a clinical experience with the biological vagaries and assimilative idiosyncrasies of real human beings will find that the authors have made biological premises too simple in order to make their conclusions more positive, but on the whole the book is not so dogmatic as those usually written by professorial teachers for the instruction of students.

The book contains a large amount of practical information and presents effectively and without prejudice apparently inconsistent correlated observations. For these reasons the omission now and then in subjects treated of facts of eminently practical importance become all the more noticeable. Failure to mention the presence of grease as an obstacle to the practical utilization of raw sewage as a fertilizer and to refer to the effect of refrigeration on trichina and tape worm cysts may be cited as two instances.

An example of the authors' way of summing up essentials is the following:

"For among all the vehicles of disease there is perhaps none more potentially dangerous to man than infected milk." The chapters on "Air in Re-

lation to Health and Comfort," on "The Relationship of Housing to Health," and on "Public Health Aspects of Tuberculosis" are to be commended as a refreshingly sensible appraisal of present knowledge regarding these subjects.

Doubtless the information contained in the book might have been condensed into fewer pages, but its verbosity is of the kind which makes it entertaining reading.

Mouth Infection Clinical histories Oliver T Osborne 119 pp New Haven The Printing Office of the Yale University Press \$2 00

Dr Osborne's book of 120 pages is divided into three parts. The first part deals with infections of the teeth and gums, the second, with tonsil infection, and the third, with Vincent's infection, the tongue, adenoids, growths and the toothbrush.

In the first part, the author gives a brief clinical story of mouth infection in which he deplors the indifference of most physicians to this phase of the practice of medicine. He classifies the physical disturbances arising from mouth infection into seven groups, among which are included heart, arthritic and eye conditions. A series of clinical histories are given in a condensed form, usually of only three or four lines.

The same procedure obtains with respect to Part Two, on tonsil infection. The subjects of Part Three are given quite cursory treatment.

As an outline of the general subject, this book may serve a useful purpose. Those seeking only an introduction to the study of the various factors associated with mouth infections, or those who want suggested to them clues to be followed up, will find material in this volume which may intrigue them and perhaps stimulate them to explore further into the subject.

The utmost condensation of the subject matter could only result in these restrictions to the book's usefulness.

Alcohol and Anaesthesia W Burridge 65 pp London Williams & Norgate Ltd 2/6

"Alcohol and Anaesthesia" is a monograph embodying the ideas of the author as to the mechanism by which alcohol affects tissues and that by which anaesthesia is produced. Burridge employs the new principles that central neurones are rhythmically active structures which possess two sources of potential for their energy manifestations, and that the physiological basis of an idea is a group of nerve cells rhythmically active in unison. He argues that we are wrong in stating that alcohol is either a stimulant or a depressant, and deduces from experiments that it is both at the same time.

We find his argument difficult to follow and his recorded experiment lacking in definite data. With his conclusions that some people may use alcohol with benefit while others ought never to use it at all, there would seem to be small ground for disagreement.

AUGUST 22, 1935

NUMBER 8

The Massachusetts Medical Society

SECTION OF DERMATOLOGY AND SYPHILOLOGY

Ball Room Assembly, Hotel Statler, Boston, June 3, 1935, 9 15 A.M.

PRESIDING

Charles J White Boston Chairman
William P Boardman, Boston Secretary

CHAIRMAN WHITE Will the meeting please come to order?

The first business before the meeting is the election of officers for next year and I will call on the chairman of the Election Committee to report the names of the nominees

Dr. FREDERICK S BURNS Boston Mr Chairman and Members of the Society—The Nominating Committee has nominated Dr Harvey P Towle for Chairman and Dr Jacoby for Secretary for the coming year

CHAIRMAN WHITE You have heard the names and the chairman is ready to bear a motion about the method of election of these two officers We have no by laws, and I would be pleased if anyone would make a motion as to how we should vote

Dr. ARTHUR M GREENWOOD I move that the sec-

retary be instructed to cast one ballot for Dr Towle and Dr Jacoby

VOICES Second the motion

CHAIRMAN WHITE Any discussion of that motion? Now for chairman of next year's section Dr Harvey P Towle of Boston And I will ask the secretary to cast a vote in favor of Dr Harvey P Towle (The secretary cast a ballot.)

CHAIRMAN WHITE Dr Towle is elected unanimously

Now the secretary? Dr Jacoby of Boston. The same motion I suppose? The secretary will cast the ballot.

(The secretary cast a ballot.)

CHAIRMAN WHITE Dr Jacoby is duly elected. Now is there any other business to come before the meeting? If not, we will proceed to the reading of the papers

Dr White then read a paper on The History of Dermatology in Boston.

THE HISTORY OF DERMATOLOGY IN BOSTON*

The Chairman's Address

BY CHARLES J WHITE, M.D.

THERE is still in existence a little broadside measuring four and one half by seven inches announcing that "The undersigned respectfully inform the medical profession of Boston that they have established a free dispensary for diseases of the skin and eye at 93 Ehot Street which will be open every morning from 10 to 12, Sundays excepted They will be happy to attend to any charity cases of these diseases which may be sent to them" This notice was dated September 24, 1860 and was signed J C White, B J Jeffries, F B Sprague and announces, apparently the birth of the specialty of dermatology in Boston

These three young physicians, together with Drs. Hasket Derby, Gustavus Hay and Henry Kemble Oliver, were fellow Bostonians, by birth or by adoption, who studied in Vienna in 1856 and 1857, in the very heyday of the Kaiserstadt when Franz Joseph and his beautiful empress were young and happy, when the music

and ballet of this gay city were the delight of the world and when the master physicians Skoda, Oppolzer, Hyrtl, Sigmund Roktansky and Hebra were the pride of the medical world When these six devotedly enthusiastic young admirers of Viennese culture returned to Boston five to become ophthalmologists and one a dermatologist they founded their so-called "Vienna Club" which was destined to endure for fifty years before any one of them should die, and is "a rather remarkable record At first their monthly meetings were largely medical with beer and pretzels as an afterthought. With the passing of the years the medical portion of the evening programs became less and less distinct, the event becoming more and more a purely gastronomic affair and the former primitive beer and pretzels assuming gradually the form of a delicious five or six course dinner with rare sherries, still rarer Rhine wines and the inevitable champagnes in temperate abundance One may well grasp the essence of this faithful and happy brotherhood when one reads this last stanza of a poem written by Dr Sprague for the twenty fifth anniversary dinner—

*Read at the Annual Meeting of the Massachusetts Medical Society Section of Dermatology and Syphilology June 3 1935
†White Charles J—Edward Wiggleworth Professor of Dermatology Harvard Medical School For record and address of author see "This Week's Issue," page 310

"Vor fünf und zwanzig Jahren wir schlossen unsern Bund
Wie Arthur's Ritter wählten wir den guten Tafel
rund
Soll man in Wien gemüthlich sein, in Boston nicht
fidel?
War wohl bei uns kein Magen leer und durstig keine
Kehl"

These were interesting men, all well born, all highly educated in languages, medicine, literature and natural history, all different in their looks, their sense of humor, their religious beliefs, their methods of life, but all indissolubly united in their first love—Vienna

One of these men must now occupy our attention for it was he who, first in Boston, devoted his medical life wholly to dermatology and continued to do so, often of necessity militantly, to within a few years of his death in his eighty-third year

James C White entered Harvard College very early in his seventeenth year and graduated in 1853 Charles William Eliot was his classmate and these two men were destined to become the protagonists in the bitter battle for a better Harvard Medical School waged against the then firmly intrenched private medical teachers in Boston

During these college years White worked faithfully at his prescribed studies but he devoted much time to the reading of good English, French and German literature, to the practical study of botany under the personal guidance of Professor Asa Gray and to the shooting and stuffing of birds for the Harvard Natural History Society of which he was Curator of Ornithology In 1856 he received from the Harvard Medical School the degree of Doctor of Medicine and was awarded a "dissertation" on Urinary Calculi

In this same year Dr White joined the Boston Society of Natural History and acted as Curator of Comparative Anatomy from 1858 to 1868 In 1856 he became a member of the Massachusetts Medical Society, was chosen anniversary chairman in 1881, was appointed orator in 1889 and served as president in 1892-1893 In September, 1856, began the year of foreign study and travel In 1857 the practice of medicine in Boston was begun In 1857 also came membership in the Observation Society and two years later in the Society for Medical Improvement, and its permanent chairmanship in 1879 In 1886 the much coveted honor of election to the American Academy of Arts and Sciences was conferred In 1876 the American Dermatological Association was founded and Dr White was chosen its first president and acted again in the same capacity in 1897 In 1907 he enjoyed the great privilege of serving as president of the Sixth International Dermatological Congress During the course of these many years Dr White was elected corresponding member of the French

and Argentine Dermatological Societies and honorary member of the Dermatological Societies of Italy, London, Vienna, Berlin, and New York and enjoyed also the distinction of having named for him a ward in the hospital of the University of Cagliari in Sicily

Dr White's first hospital position came in 1858 when he joined the staff of St Vincent's Orphan Asylum In 1860, as we have already recorded, in conjunction with Dr B Joy Jeffries he opened a dispensary for skin patients In 1863 he was appointed physician to outpatients at the Boston Dispensary In 1865 he was given the same position at the Massachusetts General Hospital and constituted the whole department Think of the growth which one generation has witnessed! In 1870 came the last change when Dr White assumed control of the skin department, a post which he held for thirty-three years And finally, with the foundation of the House Pupil Alumni Association in 1905 he became its first president

In 1863 a course of University lectures was established in the Harvard Medical School and Oliver Wendell Holmes and Dr White were appointed its first lecturers Subsequently, Dr White, with the title of lecturer, gave courses in dermatology in the department of clinical medicine In 1866 he was made adjunct professor of chemistry, and in 1871 professor of dermatology, a new chair in the Harvard Medical School and the first to be established in the United States

Despite all these arduous, quasi-public duties, time was found to mount many skeletons of animals, to act as state expert in chemistry, to prepare an almost complete herbarium of the wild flora of New England, to serve as medical examiner of a large life insurance company, to edit the *Boston Medical and Surgical Journal* and to serve as chairman of the standing committee of the First Church of Boston (Unitarian)

Throughout these long years Dr White strove persistently in public utterance and in private acts for the betterment of medical education and for the up-lifting of dermatology, and it is perhaps true that he took more pride in his share in the successful outcome of these endeavors than in any other of the many activities of his long medical career As a writer he was prolific and catholic and his titles extend to 364 numbers

Apart from medical work, the mainspring of his life, Dr White found time for wide reading and for travel, making six journeys to Europe and two to the Pacific Coast and Alaska.

He died in Boston from one of the infirmities of old age on January 5, 1916, after a life extraordinarily free from illness His was a long and useful career and he died contented

The year 1868 marks the second milestone in

Boston's dermatological history for on March 10 the City Hospital opened its Skin Out Patient Department under the guidance of Dr Howard Franklin Damon who held this position until his resignation in 1877 Dr Edward Wigglesworth was appointed his successor and served until his death early in 1896 Dr George H. Tilden received his first skin appointment at this clinic in 1881 and held his position until he resigned in 1894 Dr James S Howe began his services in 1887 and terminated them in 1907 Dr George F Harding came on the scene in 1893 and remained until his resignation took effect in 1907 Dr Harvey P Towle's name first appears in 1898 and he remained in the department until he left to go to the Massachusetts General Hospital Skin Department in 1903 Dr C Morton Smith's term of service began in 1904 and ended one year later Since then the following men have carried on the early tradition under wonderfully improved conditions

John H. Bufford	1905 (temporarily)
Francis J. Keany	1907—died on November 23 1916
Arthur P. Perry	1907-1918
Townsend W. Thorndike	1907—died on April 5 1929
William P. Boardman	1912 to date
George P. Howe	1914—died serving in the English Army in 1918
Maximilian C. von Groll	1918—died in October 1928
Walter T. Garfield	1920 to date
Jacob H. Swartz	1922 (for six months)
John G. Downing	1925 to date
Bernard Appel	1925 to date
Francis P. McCarthy	1927 to date
Abraham Blumenfeld	1929-1934
Fred N. J. Dube	1931 (served only one month)
C. Edward Green	1931 to date
Henry Benjamin	1931 to date
Irving Showstack	1932 to date
Sidney A. Sheffner	1932 to date
George Schwartz	1933 to date
Arthur M. Simmons	1933-1934
E. A. Lafreniere	1933 to date
Juan E. Clavell	1934 to date
Isadore H. Jaffee	1934 to date
Irving L. Cutler	1934 to date
James C. Brundno	1934 to date
Frederick L. Campbell	1934 to date
Ell E. Leeder	1934 to date
Charles Silverstein	1934 to date

Let us examine the lives of the pioneers of the City Hospital Clinic. Dr Howard Franklin Damon was born in Scituate, a descendant of the early settlers of this old Massachusetts town. He graduated from Harvard College in 1858 and from the Harvard Medical School in 1861 and died on September 17, 1884. He became in due time a member of the Massachusetts Medical Society, of the Boston Society of Medical Surgeons, of the American Medical Association, of the Boston Obstetrical Society, and a charter member of the American Dermatological Association.

It does not appear that he studied abroad but in 1860 he wrote a small brochure on the neuroses of the skin, in 1863 he received the Boylston Medical Prize for an essay on Leucocythaemia and in 1869 he produced an Atlas of Skin Diseases.

Dr Edward Wigglesworth, a worthy successor of a long and distinguished line of Bostonians graduates from Harvard College since 1651, was born on December 30, 1840, received his early education at the Boston Latin School and graduated from Harvard College in 1861 and from Harvard Medical School in 1865. He then gave five years to medical studies in Europe devoting himself especially to dermatology and on his return to Boston he continued this interest until his death in January, 1896. Like Dr White and Dr Jeffries ten years before him, he established a free clinic for indigent skin patients and continued this charitable work until he joined the dermatological department of the City Hospital in 1877 and became its head in 1894. For several years he was an instructor in dermatology at the Harvard Medical School. He was a member of numerous medical societies and became one of the founders of the American Dermatological Association in 1876, its vice-president in 1879 and its president in 1886. He was one of the founders of the American Archives of Dermatology and throughout his medical career was an ardent collector of dermatological books, atlases and models, in the end a splendid collection which he presented to the Harvard Medical School. Dr Wigglesworth did not limit his activities to dermatology for he was one of the founders of the Boston Medical Library, gave much time and energy to raising funds for the erection of the Boylston Street building of the Harvard Medical School, tried his utmost to secure registration of physicians in Massachusetts and worked ardently as a member of the health department of the American Social Science Association.

Dr George Horton Tilden was a native of Lowell, born on December 25, 1850 and dying in Paris May 30, 1916. He graduated from Harvard College in 1872 and from the Harvard Medical School in 1876. He served as house officer at the Massachusetts General Hospital and afterwards practiced in dermatology and syphilology and in gynecology holding positions in these medical and surgical specialties in the Harvard Medical School and at the Boston City Hospital and at the Boston Dispensary. In 1884 he became a member of the American Dermatological Association and served as Secretary from 1886 until 1889 when he became Vice-President. In 1893 he went to Japan where he entered fully into the life of the country not as a traveler but as a true lover of the Japanese people and their manners and their customs. He became intensely interested in the ancient and honorable art of sword making,

eventually being accepted into the guild, a distinct honor even for a native. Subsequently he lived in Boston for some months and finally departed for Europe where he ended his days.

Dr. James Sullivan Howe was born in Norwood, Massachusetts, on July 7, 1858 and died in Brookline November 21, 1914. He graduated from Harvard College in 1878 and from the Harvard Medical School in 1881. Then came a year's study in Vienna and the subsequent practice of dermatology for thirty years. He joined the skin staff of the Boston City Hospital in 1887 and served the hospital well for twenty years and resigned for good and sufficient reasons. He was a sound dermatologist, a hater of slipshod methods and of ignorance. In 1888 the coveted membership in the American Dermatological Association came to him and in 1911 he was elected to the Vice-Presidency.

The third epoch in Boston's dermatological history began on April 1, 1870, when according to the annual report for that year of the Massachusetts General Hospital, "Dr. James C. White tendered his resignation as Visiting Physician and asked to be appointed as physician to a separate department for the treatment of skin diseases." In compliance with his request the Trustees voted that "some vacant rooms in the Hospital be prepared for the reception of patients with such diseases and that they may be occupied temporarily and experimentally by Dr. White for the treatment of such diseases. It is understood that the measure is still in the stage of experiment."

Note the last few phrases and especially the words "temporarily," "experimentally" and "experiment." They foreboded trouble! The Trustees of those days and especially one all-powerful member of the house-staff did not take kindly to new ideas, but let Dr. White describe the sequelae in his own words (autobiographically pp. 274-275).

"In 1870, after long-continued agitation on my part a ward for the care of skin diseases was established by the trustees in the face of great opposition on the part of the surgical staff and placed under my charge. The Massachusetts General Hospital was the first hospital in this country to take such a step. It was doomed, however, to an early death. This was the year when I delivered the introductory lecture to the medical class, in which I exposed the glaring faults of the system of education then existing in our school and placed the responsibility for them where they belonged. This aroused a violent and active hostility on the part of some members of the medical faculty and hospital staff, and war was declared against the new skin ward. The class of patients to be admitted to the ward was left to be determined by the superintendent. He excluded all parasitic diseases, all chronic cases, and syphilis. He also made the statement, communicated to me by

one of the visiting staff, that he would assure the closing of the ward within six months. Owing to this lack of support on the part of the administration, the persistent opposition of certain members of the surgical staff, and the lukewarm interest of the profession in the advance of specialties, the ward was closed. The Chairman of the Trustees, in expressing his sympathy, told me that it was impossible to stand up against the domineering will of certain members of the surgical staff and one of their own body. The punishment of the physician in charge was complete."

Dr. White retreated to his Out-Patient Department and remained thus hampered until his retirement in 1902 and it was not until after this event that Dr. Charles Goddard Weld, the ever-generous benefactor of the hospital, gave his ward of twenty beds to be devoted wholly to the care of dermatological and syphilological sufferers, but during all these long years the progress of Boston dermatology had been forced to suffer by the wilfulness and shortsightedness of certain selfish men.

Despite this grievous disappointment the dermatological department of the Massachusetts General Hospital grew rapidly in the number of its patients, and in its fame. Patients came from long distances to receive its benefits and in their turn afforded an opportunity to generations of medical students, undergraduates and graduates, to study at close hand the commonest and the rarest cutaneous disorders.

For eighteen years Dr. White, single-handed, carried this ever-increasing load, no clerk, no house-officer, no nurse. What a contrast with these days of swarming attendants of all descriptions!

In 1889 Dr. John Templeton Bowen, fresh from his foreign studies, received his appointment to the skin department and by his knowledge of the latest ideas of European dermatology and his aptitude for cutaneous micro-pathology added strength and breadth to the department. He served with distinction at the hospital and at the medical school, acting from 1902 until his resignation in 1913 as head of the two departments.

Subsequent appointments to the skin clinic are as follows:

Charles J. White	1895-1927
Frederick S. Burns	1900-1926
Harvey P. Towle	1903-1925
E. Lawrence Oliver	1911 to date
Loretta J. Cummins	1916 to date
C. Guy Lane	1919 to date
Arthur M. Greenwood	1921 to date
J. Harper Blaisdell	1914-1928
John H. Bufford	1913-1927
Jacob H. Swartz	1923 to date
Ethel M. Rockwood	1928 to date
Henry W. N. Bennett	1928 to date
Mildred Ryan	1929 to date
Francis L. Burnett	1931 to date
Myer M. Tolman	1931 to date

Charles E. Wells	1932 to date
Herman Groh	1932 to date
John Adams	1933 to date

This list would not be complete without the addition of the name of Margaret ("Peggy") Reilly who received graduate training in the skin ward, saw two years of active service in Europe during the war, came in 1916 to the skin department as social service nurse and has remained ever since, one might almost say as the guiding and guarding spirit of the clinic.

It would be a distinct pleasure to write of these numerous successors of James C. White who have worked so hard and faithfully to follow in his footsteps, but it would be beyond the scope of this paper which necessarily limits itself to the lives that have been completed.

The fourth chapter of Boston dermatology opens with the foundation of the Department for Skin Diseases at the Boston Dispensary in 1873 with Dr. Francis Boot Greenough in charge.

Dr. Greenough, a member of a distinguished American family, was born in Boston on December 24, 1837 and died on October 16, 1904. He graduated from Harvard College in 1859, spent one year in the Lawrence Scientific School of Harvard, studied architecture and medicine at Pisa and Florence for two years, acted for some months in 1864 as assistant surgeon in the United States Army, served as house pupil at the Massachusetts General Hospital, received his degree from the Harvard Medical School in 1866 and pursued his graduate medical studies for another year in Vienna. From the very first he devoted his especial interests to dermatology and syphilology and as the years passed he became a prime authority in genito-urinary diseases and syphilis. For eight years (1868-1876) he was Surgeon to the Carney Hospital. From 1875 to 1895 he was Clinical Instructor in Syphilis at the Harvard Medical School. In 1879 he was elected a member of the American Dermatological Association, served as one of its Vice-Presidents in 1887 and became its President in 1891.

Dr. Greenough retired from the Dispensary in 1897 after twenty-four years of service and Dr. Ahner Post, who had been his collaborator since 1882, succeeded him and remained on active duty until 1913, continuing as consultant until his death in 1934, thus terminating a medical connection with this old institution for fifty-two years.

Dr. Ahner Post was the son of Sylvester Gilbert Langdon but at twelve years of age he adopted his mother's surname. He was born in 1844 and died on April 20, 1934. He was a graduate of Yale College in 1866 and of the Harvard Medical School in 1870. His surgical internship was at the Massachusetts General

Hospital and before his gradual and final evolution into one of the distinguished syphilologists of the country he served as surgeon at the United States Marine Hospital in Chelsea, at the Boston City Hospital for many years and at the Children's Hospital. He served as Assistant Editor of the *Boston Medical and Surgical Journal* from 1881 to 1890. He was a member of the Massachusetts Medical Society, of the American Medical Association, of the American Association of Genito-Urinary Surgeons, and of the New England Dermatological Society. He was elected to membership in the American Dermatological Association in 1892 and served as its President from 1917 to 1919. He taught syphilis for thirty-four years at the Harvard Medical School from 1882 to 1906 as Instructor, and for the following five years as Assistant Professor and during his final quinquennial as Professor. Despite his discouragingly slow apprenticeship and advancement he never faltered in his devotion to his teaching duties. This faithful characteristic marked his fifty-two years' connection with the Boston Dispensary, thirty-one of which he spent in actual work, in the subsequent years remaining on the staff as consultant.

Many men have followed these two faithful pioneers and their names and the dates of their services to the Dispensary follow:

James S. Howe, M.D.	1896-1914
C. Morton Smith, M.D.	1901-1914
J. H. Buford, M.D.	1908-1916
Clarence G. Lane, M.D.	1914-1912
J. Harper Blaisdell, M.D.	1914-1917
Loretta J. Cummins, M.D.	1916-1917
William H. Greene, M.D.	1917-1923
David L. Williams, M.D.	1917-1922
Henry J. Perry, M.D.	1919-1926
Alexander L. MacLaren, M.D.	1918-1930
Herbert H. Sawyer, M.D.	1918-1925
Clarence M. Cussellberry, M.D.	1918-1925
Consultant	1926 to date
Walter T. Garfield, M.D.	1920-1926
John F. Martin, Jr., M.D.	1920-1921
Percy L. Dodge, M.D.	1921-1925
William G. Brooks, M.D.	1922-1923
William D. Wheeler, M.D.	1922 to date
J. Leon Grund, M.D.	1923-1926
Freeman C. Wight, M.D.	1925-1929
Harry W. Hammond, M.D.	1925-1928
Arthur M. Simmons, M.D.	1925 to date
Harry F. Friedman, M.D.	1926-1932
Austin W. Cheever, M.D.	1918-1932
Russell L. Spahn, M.D.	1926-1931
Agnes G. Israelian, M.D.	1927-1931
Nels A. Nelson, M.D.	1929 to date
Israel M. Blumberg, M.D.	1929 to date
Henry C. M. DeWolfe, M.D.	1930 to date
Francis M. Thurmon, M.D.	1930 to date
Maurice M. Tolman, M.D.	1932 to date
Sidney M. Simons, M.D.	1929-30-1933 to date
Samuel S. Cargen, M.D.	1932-1933
Robert H. Goldfarb, M.D.	1934 to date

The fifth stage in the historical development of Boston dermatology was inaugurated in January 1891 when a Skin Department was insti-

tuted at the Carney Hospital with Dr John T Bowen as its head who served until 1895

The complete roster of this clinic is as follows

Dr George F Harding	1892-1902
Dr W G MacDonald	1895-1906
Dr Harvey P Towle	1897-1903
Dr F J Keany	1904—died in 1916
Dr Townsend W Thorndike	1904-1913
Dr William P Boardman	1910—resigned to enter the war
Dr G P Howe	1912—killed in the war
Dr J Brady	1915-1921
Dr W W Fennessey	1918—died in 1934
Dr William J Macdonald	To date

A sixth event in our local history was the establishment in 1913 by the Massachusetts General Hospital of a separate department of syphilis despite the bitter protests of the members of the skin staff, who felt that their expert opinion should outweigh the visionary views of certain all-powerful extremists. This revolutionary super-specialism evoked much adverse comment among American dermatologists who subsequently discussed this schism with some members of the skin staff.

A most excellent choice as chief of this department was made in the person of Dr C Morton Smith whose knowledge of this all-invading disease was most minute and whose devotion to this new clinic was and remained remarkable. To strengthen this already strong position Dr Abner Post was appointed consultant.

The following men served in this department

Dr George A Dix	1916-1924
Dr Henry D Lloyd	1916-1929
Dr Austin W Cheever	1917-1926
Dr Harry C Solomon	1920-1925
Dr Edward W Karcher	1921—died February 18, 1935
Dr Bryant D Wetherell	1919-1924

In 1929 the Hospital authorities reversed their former opinion and the care of syphilis was returned to the Skin Department with Dr E Lawrence Oliver as chief and Dr C Morton Smith as Special Consultant in Syphilis.

The seventh chapter in our history relates to the foundation of the New England Dermatological Society in 1915. This society is really the logical successor of the Boston Dermatological Club which was a small and intimate group of men of whom we shall hear more in the concluding paragraphs of this story. With the increase in the number of men devoting themselves to the study and the practice of dermatology it was felt by some of the members of this earlier club that it would be wise and fair to extend to the newcomers the advantages which the older men had enjoyed in their clinical meetings. Dr Harvey P Towle, with his usually active and progressive mind, was the ringleader in this praiseworthy development and after numerous consultations with men hereabouts and in our neighboring states he brought

this new dermatological body into being with Dr Abner Post as President, Dr Townsend W Thorndike as Vice-President and Dr Charles J White as Secretary, these men representing respectively the skin clinics of the Boston Dispensary, the City Hospital and the Massachusetts General Hospital.

This society has well vindicated the wisdom of the founders' decision and foresight. It has grown to a membership of seventy and its four annual meetings, held alternately at the Massachusetts General Hospital and at the City Hospital, allow its faithful and enthusiastic members to study and discuss many interesting, sometimes rare, examples of skin diseases.

A still further and widening development in the evolution of this Society is its coalition with all the numerous dermatological bodies scattered along the eastern seaboard from Maine to Washington, D C, into the Atlantic Dermatological Union which meets annually in one of its home ports.

The eighth milestone in Boston's dermatological progress was the founding of a skin clinic at the new Beth Israel Hospital in 1928. Dr Jacob H Swartz was appointed Chief and Dr E Lawrence Oliver, Consultant.

Since then the following men have received appointment to the skin staff:

Dr Austin W Cheever	1930 to date
Dr William D Wheeler	1930 to date
Dr Bernard Appel	1930-1933
Dr John G Downing	1930 to date
Dr Agnes C Israelian	1930 to date
Dr A Blumenfeld	1930-1934
Dr Maurice L Tolman	1932 to date
Dr Herbert Abel	1932—died in 1934
Dr Sidney Sheffner	1935 to date

The ninth and final marker (to date) in the life and steady growth of Dermatological Boston occurred last June (1934) when Dr Harvey P Towle, associated with Drs J H Blaisdell, W P Boardman, F S Burns, G A Dix, A M Greenwood, R Jacoby, C G Lane, E L Oliver, and C Morton Smith petitioned the Councilors of the Massachusetts Medical Society for permission to found a Section of Dermatology and Syphilology within the parent organization. A hearing was given by the Councilors and with only faint opposition the petition was granted and let us hope that this section may continue an enduring success as long as the science of dermatology remains a separate branch of general medicine.

Such is the formal though necessarily curtailed account of the development and evolution of Boston dermatology, a branch of medical science which has never been justly recognized or treated by the higher local medical hierarchy but which, despite many rebuffs and disappointments, has left its mark on the world's dermatological pages.

For the sake of future students of our dermatological past it would be a pity not to add

as a concluding chapter a verbal picture of the pioneers as they sat at table after the conclusion of the evening clinical meeting of the Boston Dermatological Club which was founded perhaps in 1888 and continued with changing personnel until it was fused, as previously stated, with the larger and more comprehensive New England Dermatological Society.

This earlier group was small and intimate, its patients were few but well chosen, discussion was informal but everyone present contributed his best. Then followed a suitably simple but delightfully friendly supper where the younger members listened to the wise and educated remarks of the elders.

Such a meeting took place in November, 1895. Dr. George H. Thibodeau was in Japan but the other charter members and one initiate were present.

Dr. James C. White, erect, dignified, ruddy checked, white-haired and bearded, courteous, stern in his professional moments but a delightful companion when "off duty" and able to talk authoritatively on many subjects.

Dr. Francis B. Greenough, distinctly tall but somewhat stoop-shouldered, an aristocrat to the tip of his fingers, with a charming smile playing about his mouth, a great lover of shooting and always accompanied on the street by one or more pointer or setter dogs, a delightful conversationalist.

Dr. Edward Wigglesworth, rather thick set, strikingly red faced with contrasting abundant, short-cropped, upstanding white hair, much in earnest, full of Latin and Greek quotations, a man to be admired and trusted like all his family for generations in America.

Dr. Abner Post, of good height with stooping shoulders, white-bearded, concealing evidently behind that beard a good many thoughts, wise, amusing and often cryptic, a man who had to be drawn out, a man of sterling qualities, perhaps unappreciated and hence introverted, a patient man and one ever thoughtful of an ambitious student.

Dr. James S. Howe, a large tall, athletic, out-of-door, bronze-faced man with a graceful moustache partially concealing a left-sided facial paralysis, a distinctly forthright man hating shams, impatient of stupidity, a cheerful, pleasant companion.

Of Dr. John T. Bowen we would like to say much but our tongue is tied for in this narrative personal remarks are limited to those who have passed on.

In subsequent years Dr. George F. Harding, Dr. John H. McCollom, Dr. Frederick S. Burns, Dr. C. Morton Smith and Dr. Harvey P. Towle joined the Club and with the passing years our elders, unhappily for us, disappeared from the scene but became unforgettable shadows of the irretrievable past.

The writer wishes to acknowledge with thanks his debt to the various hospital superintendents who have furnished him with their respective rosters and to certain biographers who have given him clues to the life histories of the men who figure in these pages.

CHAIRMAN WHITE: Gentlemen—The next paper of the meeting will be Oral Manifestations of Bismuth by Francis P. McCarthy of Boston and Smith O. Dexter Jr., of Boston.

ORAL MANIFESTATIONS OF BISMUTH*

BY FRANCIS P. MC CARTHY, M.D.,† AND SMITH O. DEXTER, JR., M.D.‡

THE use of bismuth in the treatment of syphilis is now so widespread that it is not generally known how recently the drug has come into use. Although bismuth was employed by Balzer as early as 1889 to treat syphilis, it fell into disrepute because of the very toxic preparation which he employed. Little was heard of bismuth in this connection until 1916 when Sanborn and Robert observed its value in chicken spirillosis. Six years later in 1922, following experimental work on rabbit syphilis, Sazercote and Levaditi used it again in the treatment of human syphilis. Since that time bismuth has attained a position in the treatment of syphilis

second only to that of the arsenicals and has almost displaced the use of mercury.

The three drugs commonly used in syphilis have widely different properties from a therapeutic and toxicological standpoint. Arsenphenamine has the most active spirocheticidal power of the three and sterilizes infectious lesions with great rapidity. Its beneficial action is due almost entirely to this ability to kill the organisms. The exact mode of action of bismuth in syphilis is undetermined at the present time. That spirochetes disappear from infectious lesions under bismuth therapy has been amply demonstrated, but how far this action is due to a direct spirocheticidal power or to stimulation of the patient's resistance is unknown. Regardless of these theoretical considerations, bismuth is daily proving itself to be a practical and invaluable adjunct in the treatment of all stages of syphilis. Mercury, on the other hand, has

Read at the Annual Meeting of the Massachusetts Medical Society, Section of Dermatology and Syphilology, June 3, 1923.
†McCarthy, Francis P.—Professor of Oral Medicine, Tufts College Dental School, Dexter Smith O., Jr.—House Physician, Fourth Medical Service, Boston City Hospital. For records and addresses of authors see "This Week's Issue" page 517.

a negligible direct effect on the organisms, but probably owes its action to its stimulating effect on the resistance of the host although the exact mechanism of this effect is unknown

From the viewpoint of toxicity the three drugs differ greatly. Arsphenamine has marked toxic properties which have been thoroughly investigated, and are generally known, while the stomatitis, nephritis, and general debilitating effects of mercury are also well known. The toxicology of bismuth is being extensively studied, and while it is the least injurious of all the drugs employed, yet it is far from innocuous.

Within the last few years a vast number of preparations have appeared on the market, differing widely in bismuth content, solubility, and method of administration. The most important preparations may be roughly subdivided into five groups:

- (1) Water soluble in water solution, e.g., bismuth sodium tartrate
- (2) Water insoluble, suspended in water, e.g., bismuth metal
- (3) Water soluble in oil solution, e.g., bismuth potassium tartrate
- (4) Oil soluble in oil solution, e.g., bismocymol, biliposal
- (5) Oil insoluble, suspended in oil, e.g., bismuth salicylate

These preparations show definite differences in rate of absorption and excretion, although in the first four groups the difference is not very great. However in the last group, e.g., bismuth salicylate, absorption and excretion are greatly delayed and hence accumulative mild toxic phenomena are more pronounced.

Bismuth is now a one route drug. Oral and injection methods have been proved valueless, and the intravenous route has been shown to be dangerous and ineffective. Beerman pointed out that almost all the immediate fatalities during bismuth treatment were due to intentional or accidental intravenous injection. The reason for its high toxicity intravenously is the close approximation of the toxic and therapeutically effective doses, as the toxic dose is 100 mg., and the minimum curative dose 90 mg. On the other hand, with the intramuscular route the toxic dose is three to ten times the effective therapeutic dose.

The rapidity with which bismuth is absorbed from the injection site varies with the type of preparation employed. With the more rapidly absorbed preparations the maximum bismuth concentration in blood and tissues occurs within a few hours. In experimental work it has been found that the principal depots of storage are the kidney, heart, lungs, and liver. It has also been observed that there are deposits of bismuth sulphide in the cecum. Probably the factors determining its presence here are sim-

ilar to those which cause precipitation in the buccal mucosa. The question of its penetration into the nervous tissues has been widely discussed, but according to Klauder and Brown the concentration in spinal fluid in human subjects and in the brain of experimental animals is almost negligible regardless of the preparation employed.

The question of its excretion has been carefully studied by Hanzlik and Mehrtens, Sollmann et al., and others. With easily absorbed preparations bismuth appears in the urine the day after administration, reaches a maximum on the second or third day, and then gradually diminishes in amount over three weeks when perceptible excretion has nearly ended. The excretion curve is much the same with water soluble, oil soluble, and oil suspension of the tartrate preparations, though time intervals are longer with the last two groups. Bismuth salicylate stands in a class by itself because of its greatly delayed absorption and excretion. Mehrtens and Hanzlik found that with the water soluble preparations in aqueous solution, after one or two injections had been given (equivalent to 22 or 44 mg. of bismuth) 45.2 per cent was excreted in the course of two weeks in the urine. Sollman et al. found lower figures with excretion from fifteen per cent to twenty-five per cent, in three weeks for all preparations except the salicylate. With this last preparation only four per cent was excreted in three weeks, though a longer follow-up period would greatly raise this figure, since minute amounts continue to be excreted for several weeks.

The toxic manifestations of bismuth are numerous and a vast number of cases of poisoning have been described. The skin, blood, liver, kidneys, gastro-intestinal tract and nervous system have been reported as the chief sites of strong toxic effects of the drug. By far the most common manifestation is bismuth stomatitis. Vigne in a series of 76,478 injections found that treatment had to be stopped in from eight per cent to ten per cent of cases. The reasons for ceasing treatment were classified as follows:

Stomatitis	72%
Asthenia and "grippe"	10%
Local pain (severe)	9%
General reactions	6%
Cutaneous eruptions	5%
Abscess (at site of injection)	3.3%

Irgang et al. have studied the oral complications of bismuth therapy in a large number of cases. They found a line in the gums in nearly 100 per cent of cases under treatment. Oral sepsis and the use of soluble preparations of bismuth seemed to hasten the production of this line. Any condition causing irritation of the gums predisposed to bismuth deposits and led to intensification of the local reaction. When deposits became sufficiently marked and coincident infection was present, stomatitis with ac-

tual necrosis and secondary infection was common. Lewin (quoted by Mora) divided the oral changes into four stages:

(1) Slight pigmentation occurring first on the lower incisors where tartar and organic debris were present. (2) A gingivitis developing in the region of the pigment. (3) and (4) Ulcerative and gangrenous patches in neglected mouths. In support of the fact that oral sepsis strongly predisposes to bismuth stomatitis it has been noted that significant degrees of involvement are much less common among well-to-do patients than in clinic practice.

This present study is based on a series of 511 consecutive patients under present or recent bismuth treatment in the Skin Out Patient Department Clinic of the Boston City Hospital. The mouth of each patient was examined with special attention to the presence or absence of bismuth pigmentation, the condition of the gums and teeth, and the general oral hygiene. The adjacent buccal mucosa was carefully examined for the presence of contact areas of bismuth pigmentation. The amount of bismuth given the time interval since the last injection, and the period over which treatment had been carried out were obtained from the Out Patient Department records. Those cases with marked oral involvement had urine and blood examinations to exclude severe renal and bone marrow complications. The results are presented in detail along with the case reports of two patients with gangrenous stomatitis.

The bismuth preparation used in this clinic was the suspension of the insoluble bismuth salicylate in oil in dosage of from one to two cc. (1 to 2 grains) per week. The basic plan of treatment in this clinic at the same time this study was made was as follows:

(1) Primary and secondary cases. Twenty weekly injections of neoarsphenamine followed by fifteen weekly injections of bismuth salicylate followed by a four weeks' vacation. Subsequent courses of ten neoarsphenamine and fifteen bismuth salicylate injections.

(2) Tertiary. Ten neoarsphenamines followed by fifteen bismuth injections, followed by a four weeks' vacation and repetition of the course.

The reasons for the use of the insoluble preparation are as follows:

(1) Given in small dosage a continuous supply of heavy metal is obtained over the whole treatment cycle.

(2) The difficulty in making patients come for treatment even as often as once a week makes desirable the use of a preparation which is absorbed slowly and whose action is prolonged over a long period of time.

(3) The rarity of severe toxic reactions and the excellent therapeutic results have justified the choice of this preparation.

We have summarized the results of our studies in tabular form in presenting our findings.

In the study of the incidence of bismuth pigmentation of a series of 511 luetic patients, 400 of whom were actively under treatment and the majority of the balance treated within six months with bismuth salicylate, a very high incidence of pigmentary deposit of bismuth sulphide was noted in the oral cavity.

511 CASES

Pigmentation alone	194 cases
Pigmentation with gingivitis	142 cases
	386—65%

Of the 400 patients actively under treatment 278 or approximately seventy per cent showed pigment deposits in the gums or elsewhere in the buccal mucosa. Sixty patients in this group were edentulous, four of whom showed pigmentation. Eliminating this edentulous group 340 dentulous cases showed pigmentation in 274 or eighty six per cent.

In the remaining group of 111 cases treated with bismuth within a year, fifty-eight patients or fifty two per cent still showed pigmentary deposits of bismuth. Eliminating twenty-one edentulous cases, three of whom showed pigmentation ninety dentulous cases in this group showed pigmentation in fifty five cases or sixty one per cent. Three hundred and thirty six cases showed pigmentation out of the total of 511 cases studied or sixty five per cent who were actively or recently under treatment with intramuscular bismuth salicylate therapy.

There was an associated gingivitis in 142 of the 336 cases. Whether this gingival inflammatory reaction was due to the bismuth deposit it is impossible to say as undoubtedly many of these cases had preëxisting gingivitis.

EDENTULOUS MOUTHS SHOWING PIGMENTATION

51 Edentulous mouths—7 of which showed pigmentation

35 males	3 with pigment
46 females	4 with pigment
	7 or 14%

Buccal mucosa of cheeks	3
Tongue	1
Vestibule of mouth	2
Gums	1
	7

Only nine per cent of the edentulous group showed any evidence of pigmentation—all showing very slight evidence requiring careful search of the oral cavity for evidence of the deposit. The irritating pressure of dentures was the important single factor in this group.

GRADE OF PIGMENTATION

Grade I	184
Grade II	123
Grade III—with contact pigmentation	80

The pigmentation was graded according to the intensity of the gingival staining with special reference to contact pigmentation

Grade I Cases showing a faint greyish or slaty black gingival linear pigmentation, confined to the gum crest localized or generalized in distribution and not associated with any clinical evidence of inflammatory reaction

Grade II These cases show a broader line of pigmentation, with a definite black discoloration of the gingivae, or pigmented areas other than the contact cases

Grade III All of the intensely pigmented cases were so classified, with an associated contact pigmentation of the opposing buccal mucosa. Our first impression in this type of case was that the process of imbibition was responsible for this pigmentation but we are now satisfied that the pigmented areas are in direct contact with the tartar on the opposing teeth and definitely indicate a blood stream deposit at the points of lowered resistance (*locus minoris resistentiae*)

LOCATION OF PIGMENT	
Generalized gingival pigmentation	129
Localized gingival pigmentation	168
Tongue	10
Buccal mucosa of cheeks	7
Buccal mucosa of lower lip	8
Buccal mucosa of upper lip	6
Soft palate	5
Region of sublingual duct orifice	2
Tonsil	1

It was noted that an overwhelming number of cases, or ninety-two per cent, showed gingival involvement alone, and that most pigmentation that occurred other than on the gums was of the contact type. It was noted that localized collection of pigment was invariably in relation to tartar deposits at the necks of the teeth and the common location was the lingual surface of the lower central incisors. The labial surfaces of the lower and upper central and lateral incisors were also frequently involved

Extragingival pigmentation other than that caused by contact with teeth occurred more frequently on the dorsum of the tongue and the soft palate, was usually very slight, and was characterized by small pigmented areas

The most important single factor that was noted in all cases studied showing gingival pigmentation was the presence of tartar at the necks of the teeth. The incisor teeth where tartar is prone to be deposited in excess was the almost constant location for excessive deposits of pigment

Frequently the lingual and labial aspects of these teeth represented the only demonstrable deposit of pigment and pigmentation may easily be overlooked unless one examines particularly the lingual aspect of the gums of the lower central incisors

It was noted that pigmentation was rare in children under ten years of age as only one case out of ten examined showed a slight deposit on the gingival crest of the lower incisor teeth. The absence of tartar formation is undoubtedly the important factor for lack of pigmentation in youth

RECENTLY ON OF PIGMENTATION AFTER TREATMENT SHORTENS AT WITH BISMUTH			
Preparation	Positive Pigment	Negative Pigment	% Positive
For two injections to 22 or 24 excreted			
After 1 Solh	12	14	46%
After 2 on jhs	18	22	45%
After 3 ,ths	12	18	40%
After 4 ,ths	5	15	25%
After 5 months to 9 months	11	41	21%

This table represents the group of dentulous cases that were under treatment with neoarsphenamine after finishing courses of bismuth therapy. Forty-two showed pigmentation and fifty-four were negative for pigment three months after discontinuing treatment. Our study indicates that bismuth deposits are very slow to disappear from the gums especially in marked cases, and show pigment even a year after treatment has ceased

CASE 1

J. S.—Aged sixty-four, white, male, single
Complaint Sore mouth for three or four days
Present Illness Patient has been receiving antiluetic treatment in the Out-Patient Department for a few weeks. Patient is a tertiary luetic, positive Wassermann test, although there is no evidence of skin or mucous membrane lesions due to syphilis. The

CONDITION OF THE GUMS AND GENERAL ORAL HYGIENE

		Male	Female	Total	Percentage
Good	164	47	54	101	62%
Fair	150	88	40	128	85%
Poor	116	68	39	107	92%
Edentulous	81				
511				336	

It will be noted from the above table that as would be expected the patient with poor oral hygiene and associated gingival lesions showed a much higher percentage of pigmentation

patient received three doses of bismuth salicylate at weekly intervals and three days after receiving the third dose reported at the Out Patient Department complaining of a sore mouth
Examination showed a large necrotic and gangrenous

lesion involving the buccal mucosa of the left cheek extending from the third molar region to the cuspid region about the size of a twenty-five cent piece. There was marked swelling of the cheek externally and a very foul odor to the breath. From the buccal mucosa to the right cheek in relation to the upper third molar is an area on the gum margin of the third molar tooth in relation to an area of tartar formation.

Smears of the gangrenous lesion were positive for Vincent's spirochete and fusiform bacilli. The lesion was treated with a neocarsphenamine paste. Four days later the patient visited the clinic again

1 Case No. 1—J. S. Gangrenous stomatitis buccal mucosa of left cheek showing extensive necrosis, gangrene and pigmentation.

and was given a dose of bismuth by mistake. Two days later the patient returned and showed a marked extension of the process which had extended up in the soft palate as far as the left external commissures of the lip. He was advised to enter the hospital for treatment but refused. The local lesion was treated with five per cent chromic acid and the patient was given intravenous injections of sodium thiosulphate. Patient remained ambulatory during the active stage of the condition. After two weeks time the process began to show marked improvement. Vincent's organisms disappeared locally and the local pain and discomfort rapidly improved. As the necrotic and gangrenous areas began to improve there developed a deep black pigmentation in the periphery of the area involved and on healing the entire area showed extreme pigmentation.

Laboratory Findings Hemoglobin 70% Red blood count 4 800 000 White blood count 8 100

Differential count

Polymorphonuclear leucocytes—80%
Large mononuclear leucocytes—8%
Small mononuclear leucocytes—11%
Eosinophiles—1%

Polymorphonuclear leucocytes principally young forms and slight decrease in the number of blood platelets

Urine Specific gravity 10/10 Albumin, a trace Sediment shows few pus cells and rare hyaline casts

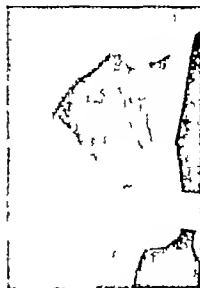

Subsequent History of the Case Examination of the month three months after the gangrenous process showed a residual pigmented lesion of the buccal mucosa of the left cheek about the size of a fifty cent piece with a small pockered scar. The pigmentation on the right cheek was still present.

In addition to the pigmentation of the cheek there still was the pigmentation present at the gingival margin.

Biopsies were taken of gingivae and buccal mucosa of cheek two months after healing of the gangrenous process. Blood and urine examinations were

essentially the same as on first examination. Wassermann test, positive

Comment This case is essentially the same type as Case 2. He shows a chronic nephritis with a marked susceptibility to bismuth deposit probably due to faulty elimination through the kidneys. The gangrenous process was much more severe and was aggravated by the dose of bismuth salicylate given

2 J. S. Three weeks after treatment showing gangrenous area filled in, with some of pigmentation at the periphery

after the gangrenous process had begun. The secondary Vincent's infection responded promptly to local treatment with neocarsphenamine and chromic acid. The biopsies taken during the gangrenous stage and two months later are discussed under pathological findings

CASE 2

M. B.—Aged sixty colored, married male

Past History First indication of lues two years ago when he had an ulcer on his left knee. Positive Kahn was found. The patient had been under treatment in the Medical Out Patient Department for last two or three years for hypertension and nephritis. No cardiac symptoms except mild dyspnea.

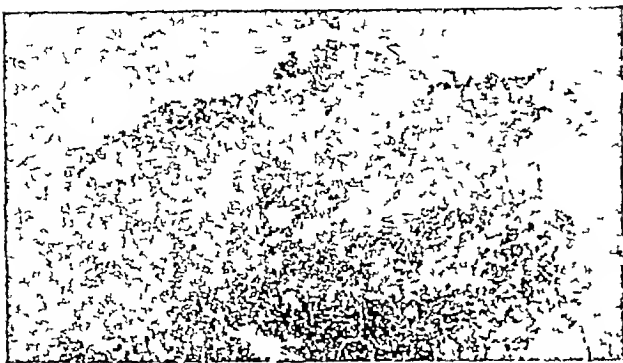

November 20 1932, after twelve treatments with bismuth salicylate the patient developed bismuth line and exfoliative dermatitis on trunk and limbs (Last neocarsphenamine four months before). Given three injections of sodium thiosulphate and admitted to Skin Service where he stayed seven weeks

Present Illness The patient has been receiving anti-luetic treatment in the Out Patient Department for two years. Analysis of Out Patient Department record showed he had had three courses of neocarsphenamine and bismuth salicylate punctuated by several self-imposed vacations. No reactions with neocarsphenamine but during each course of his mouth toxic symptoms developed a bismuth line and exfoliative dermatitis after twelve injections for which he was admitted to the hospital abdominal pain after three treatments on another occasion and his present trouble after eight treatments. His last course of treatment was started in January 1934 and eight treatments were given, the last four at weekly intervals the month before admission. Three days after last treatment the gums became sore and on returning for another his oral condition was so bad that admission was advised

Physical Examination A thin, poorly nourished man, not acutely ill. Face slightly swollen. Teeth consist of a few dirty discolored carious snags on lower jaw although most of upper present but in similar condition. On free margin of gums around

teeth was a heavy black line with associated redness of gums. Mucous membrane of mouth red and inflamed. Opposite upper and lower incisor teeth and molars there were heavy black deposits in buccal mucosa of the cheek and upper and lower lips. The rest of the physical examination was negative except for cardiac enlargement with murmur at aortic area, and a blood pressure of 240/140.

There is an ulcerative gangrenous lesion involving the gingiva in the region of the upper right

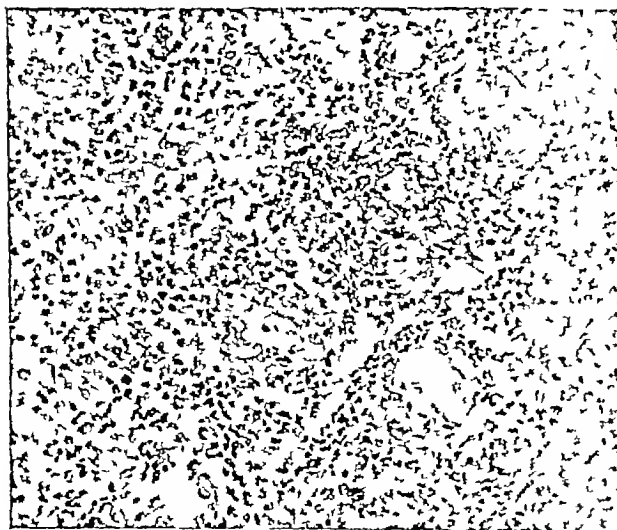

3 Section through gangrenous lesion of cheek showing necrotic exudate on the surface zone of pigmentation near surface wide zone of polymorphonuclear leucocytic infiltration and deeper zone of pigmentation and thrombosis of capillaries

cuspid and bicuspid region measuring about 1 cm in diameter. There is an associated fetid odor to the breath.

Laboratory Findings *Urine Examination*, slight possible trace to trace of albumin. Sediment fine granular casts on three occasions. White blood cells but no red blood cells.

Blood, hemoglobin 90 per cent. Red blood count 4,750,000. White blood count 4,200 to 7,300. Smear normal except for thirteen per cent eosinophiles. Smear buccal ulcerations positive for Vincent's or-

4 High power showing thrombosis of vessels in deeper zones with some pigmentation

ganisms, but negative after neoarsphenamine past application. Nonprotein nitrogen, 43. Kahn, negative.

X-ray of chest, hypertensive deformity of heart, bronchiectasis right middle lobe.

X-ray of teeth, marked oral sepsis with five abscessed teeth with marked periodontoclasia.

Clinical Course In the ward, the patient's oral condition improved rapidly with sodium perborate mouth washes and intravenous sodium thiosulphate. The gangrenous area rapidly cleared up, although the heavy black deposits remained. The patient was discharged after two weeks, condition improved, to the Out-Patient Department. The chart was normal throughout. The patient three months after discharge shows pigmentation of the gums.

Comment This patient as indicated in the past history showed previous severe reactions to bismuth therapy. In the first course he developed an exfoliat-

5 Bismuth pigmentation of gingiva with contact pigmentation of lower lip

ing rash after twelve treatments with bismuth salicylate. Again after three treatments he developed abdominal pain and treatment was discontinued. The oral gangrenous process followed after the eight treatments of bismuth salicylate.

The complicating nephritis was undoubtedly a factor in the production of the gangrenous stomatitis and previous reactions due to faulty elimination.

The incidence of necrotic or gangrenous processes in the mouth from bismuth salicylate therapy is extremely rare as these two cases represent the only ones that developed in the past eight years in the treatment of many thousands of luetics with this form of therapy.

Both of these cases were suffering from chronic nephritis and a relatively small amount of bismuth was given in each case. It will be noted that the response to treatment in these two cases was fairly prompt after the administration of bismuth was stopped, although the process at one time seemed to be spreading rapidly in Case 1.

Pigmentation by itself apparently has very little untoward effect on the patient but cases which show extensive gingival and contact pigmentation with marked gingivitis where relatively small doses of bismuth are given should be watched very carefully and a urine examination made for possible nephritis.

PATHOLOGY

The deposit of pigment in the gingivae and buccal mucosa of the mouth occurs in the corium and particularly in the papillary region. It is found as black amorphous granules of pigment tending to be deposited in the endothelium of the blood vessels and connective tissue cells al-

though much of the pigment seems to lie extracellularly free in the tissues. There is an associated inflammatory reaction characterized by an increase in lymphocytes and a few polymorphonuclear and plasma cells. There is no pigment found in the stratified squamous epithelium. In the gangrenous process the zone of pigmentation is very pronounced and there is an associated infiltration with polymorphonuclears with fibrin formation and capillary thrombi. A secondary infection with the Vincent's organisms is responsible, however, for the marked necrosis and gangrene which is superimposed on the necrotic process. The pigment is very slow to be absorbed or carried away by lymphatics and the average case of moderate or marked pigmentation takes several months to disappear.

The mechanism of formation of these gingival linear deposits is somewhat in doubt, but presumably it is the precipitation of bismuth sulphide around the capillaries. It is suggested that hydrogen sulphide formed from the decomposition products of food is absorbed by the gingival mucosa and there comes in contact with the soluble bismuth salts which have passed through the capillary walls.

The insoluble sulphide of bismuth thus produced acts as a local irritant and gives rise to a low grade gingivitis.

TREATMENT

The treatment of bismuth pigmentation is essentially prophylactic as indicated by the high incidence of the disease in the mouth that shows the presence of tartar or preëxisting pyorrhea and poor dental hygiene. A preliminary scaling of the tartar of the necks of the teeth before bismuth therapy is instituted and adequate care of the mouth during treatment will definitely tend to minimize the incidence of pigmentation.

In the treatment of the focal necrotic and gangrenous cases the use of a neosarsphenamine paste or five per cent chromic acid locally, if Vincent's organisms are found, is especially useful in controlling the secondary infection with these organisms. Internally, sodium thiosulphate injections are desirable although there is no definite evidence that this preparation has a specific effect in neutralizing the toxicity of bismuth preparations. Elimination through the kidneys or intestinal tract is very desirable in the toxic cases and if associated with leucopenia, the use of pentose nucleoid may be tried. Our two cases responded, however, with a minimum of treatment but in fulminating cases all the above suggested methods of treatment should be applied.

A selected group of severe gingival and contact cases was treated at the Tufts College Dental School clinic by thorough cleansing of the teeth removal of tartar deposits and debris to

hasten the absorption and disappearance of the mucosal pigmentation.

Many of these cases had not used tooth brushes for years and showed the results of this marked neglect in oral hygiene.

Brilliant results were obtained in this selected group of pronounced pigmentation with gingivitis in hastening the disappearance of the pigment deposits and allaying the inflammatory reaction of the gums.

COMMENT

The high incidence of bismuth pigmentation in the mouth taken in a series of 511 cases of syphilis under treatment in a hospital clinic indicates in this group of patients that local oral hygiene and tartar deposits seem to represent the important factor in this group.

The contact buccal mucosal pigmentation is shown to be definitely due to irritation from the opposing gingival irritant which is essentially tartar. Severe cases of gingival pigmentation and inflammatory reaction are relatively few in number and over a period of about ten years since this bismuth preparation has been in use the number of cases of necrosis and gangrene has been extremely rare. Therefore, this drug can be considered safe as a therapeutic agent in the treatment of syphilis as the presence of pigmentation and mild gingivitis seems to have no deleterious effect on the general health of the patient.

A series of urinary examinations on a selected group of severe cases of pigmentation with gingivitis were negative for evidence of nephritis. Both the cases herein reported had chronic nephritis and this condition is definitely a factor in the production of local gangrenous processes although susceptibility to the drug undoubtedly may play an important rôle.

Examination of the blood of a small group of cases showed no dyscrasia related to bismuth therapy.

In contrast to the hospital cases studied in this series a small control group of office patients under bismuth salicylate therapy showed a low incidence of pigmentation, about five per cent. These findings confirm our deductions that poor oral hygiene is the important factor which predisposes to pigmentation in the oral cavity.

SUMMARY OF FINDINGS

- 1 The incidence of pigmentary lesions of the oral cavity in a study of 511 dentulous patients receiving bismuth salicylate by intramuscular injection was approximately eighty per cent.
- 2 Edentulous mouths under treatment with bismuth showed a low incidence (9 per cent) and of a mild character.
- 3 In grading pigmentary lesions it was noted that the severe cases showed a so-called

contact pigmentary deposit in the opposing buccal mucosa

4 Two cases of gangrenous stomatitis (bismuth) with the pathological findings are discussed

5 Tartar accumulation with associated gingivitis was the important single factor predisposing to pigmentation

6 The incidence of bismuth pigmentation in private cases was very low about five per cent.

7 Chronic nephritis with associated faulty elimination is undoubtedly an important factor in the causation of gangrenous lesions of the oral cavity

8 Removal of tartar deposits with improved dental hygiene hastens the disappearance of pigmentation and tends to prevent further deposits

DISCUSSION

CHAIRMAN WHITE The discussion will be opened by Dr Austin W Cheever of Boston

DR. AUSTIN W CHEEVER, Boston I don't see that Dr McCarthy has left very much for me to say He has described these lesions well and has photographed them He has done some good work on pathological studies

I have been particularly impressed as he pointed out, by the small number of cases of children who show any evidence around the teeth Even with our congenital syphilitic children, whose mouths are in very bad condition when they come to us, and where it is very difficult to get them into proper condition, there is very little pigmentation

I was surprised at the figures he quoted for the amount of actual stomatitis as compared with pigmentation It did not seem to me I had seen so much It might be well to remind ourselves of the difference from the days of mercury, before bismuth had been established as a useful drug, when we used to see a great deal of stomatitis, very foul breath, the loosening and loss of a number of teeth, and sometimes osteomyelitis of the jaw

CHAIRMAN WHITE Dr William P Boardman of Boston will continue the discussion

DR. WILLIAM P BOARDMAN, Boston The doctor spoke of intravenous bismuth not being quite so effective I take issue with him there We tried intravenous bismuth for a while, and found it very effective It was also very fatal, although we did not have that experience, so we stopped using it For healing the lesions, it was just about as effective as arsphenamine

He spoke of nephritis, and yet several cases have been reported of syphilitic nephritis where the patients did not do well with mercury but did do well with bismuth, but certainly it is a fact that if the kidney is not doing well, you have to watch the patient when you are using bismuth, although not so closely as with mercury The bismuth is secreted a good deal in the mouth through the mucous membrane I suppose that has something to do with the fact that these bismuth lesions appear in this region One of the earliest observations in bismuth therapy was the rapid healing of numerous membrane lesions

The absence of sore mouth and foul breath was what I was never able to explain in these cases In using mercury, before you get the lesions in the mouth, you often notice foul breath, and the patient complains of toothache With bismuth we get marked

gingivitis, yet the patient complains little, and when the treatment is ended it clears up in a short time

The doctor spoke of Vincent's infection The question arises whether it is a Vincent's infection or a bismuth condition, but the fact is that Vincent's organisms are found almost always in these bismuth stomatitis cases, probably as a secondary invader

The doctor shows how the bismuth does not deposit in the epithelium Under the microscope it is underneath the epithelium, and very marked in the papillae

Moore has called attention to a curious coincidence In giving silver arsphenamine and bismuth together, the patient developed argyria after a large amount of both, but did not develop argyria without the bismuth Possibly if you are giving silver arsphenamine, it would be better not to use the bismuth. Silver arsphenamine is not used much around here

As to the frequency of bismuth stomatitis, oral sepsis is certainly one of the underlying causes, as the doctor has noted We must look at the lingual aspect of the gums as well as the outside The pigment first shows on the lingual side of the gingivae

We are using bismuth almost to the exclusion of mercury, and I often wonder if there are really any definite statistics about the value of it. Certainly it is rather more pleasant to take, and the patients keep coming more regularly under bismuth than they ever did under injections of mercury, but I am not convinced that it is so much better in its permanent effects than mercury I do not believe we have any statistical evidence to that effect In clearing up the lesions, it works about as well as the mercury, if not better, but to give up mercury entirely, it seems to me, is a great mistake until we know more about the later results of bismuth Certainly bismuth should not be given alone, we know that much But whether there should be some mercury given in the routine treatment of syphilis, and not just arsphenamine and bismuth, is still to my mind a moot question

CHAIRMAN WHITE The question is open to general discussion

DR. C. MORTON SMITH, Boston I wish to say just a word in connection with what Dr Boardman has just stated, as to the effectiveness of mercury in certain cases that apparently have failed to show a satisfactory response to arsphenamine and bismuth It is one of the drugs to be kept in mind, and I think with a properly prepared mercurial cream used with discretion intramuscularly, results are often obtained which you fail to get with arsphenamine and bismuth, e.g., the cessation of recurrent lesions and the production at times of negative serological reactions

DR. RUDOLPH JACOBY I would like to ask Dr Smith the composition of the cream which he has mentioned.

DR. SMITH The formula is metallic mercury 20, anhydrous lanolin 30, chlorotone 2, heavy olive oil (Anton Chiris) 100 It must be rubbed up in a mortar with the oil very thoroughly, till no globules of mercury can be seen—M v = 1 grain of metallic mercury,—an average dose intramuscularly Massage the site of the injection thoroughly

CHAIRMAN WHITE I will call on Dr McCarthy to close the discussion.

DR. FRANCIS P MCCARTHY I neglected to state that the incidence of bismuth pigmentation in the oral cavity on private patients is very low as com-

pared with hospital cases. Probably less than 10 per cent of private patients show any pigmentary deposit in the gingivae. I am convinced that tartar is the outstanding factor as the predisposing irritant resulting in the collection of pigment in the gum tissues. It is very difficult to correlate the hydrogen sulphide theory as the important factor in the deposit of bismuth sulphide in the tissues es-

pecially where there is no break in the continuity of the overlying stratified squamous epithelium so that the actual reason for the deposit still remains somewhat obscure.

CHAIRMAN WHITE. The next paper is entitled "The Treatment of Psoriasis with an Organic Sulphur Compound" by Francis M. Thurmon of Boston.

THE TREATMENT OF PSORIASIS WITH AN ORGANIC SULPHUR COMPOUND*

BY FRANCIS M. THURMON, M.D.†

THE nearest approach of any study to the present investigation is that of L. Bory¹ who, in 1907, prepared a "glycerine in-sulphur" compound which he used in many disorders, including two patients with psoriasis. Bory's preparation contained "besides sulphur in colloidal and dissolved states, traces of acroleine, mercaptans and allylates." Small doses of this mixture were injected intragluteally and into the plaques of psoriasis, but the results were deemed too inconsequential to be published at that time. Later in 1917, '18 and '32, when colloidal sulphur began to assume greater importance in medicine, Bory cited his previous investigations, but revised his original formula to include not only sulphur in suspension but also guaiacol, eucalyptol and oil of sesame. This modification formed a true "colloid solution" which, according to Bory, when injected intramuscularly exerted a remarkable effect upon psoriasis.

Of the various preparations of sulphur employed in medicine colloidal sulphur has seemed to be the most effective. Its efficiency is based upon the finely subdivided state of its particles which provides a vast surface area in proportion to the total mass. Colloidal sulphur is the closest approach to a true solution of sulphur that is of effective application thus far described. When injected intramuscularly the colloidal preparations cause leukocytosis and fever. When given intravenously it produces a rise in body temperature to 103°F in from seven to ten hours that remains from thirty to forty hours. Thus, its usefulness in producing hyperpyrexia has been utilized in treating dementia praecox, general paresis, Wassermann fast syphilis, paralyses and other disorders of nerve and mental origin.

That the dermatological application of colloidal sulphur has certain limitations was shown by Miller² who stated that its value for cutaneous conditions was limited to those disorders which had responded to other forms of sulphur therapy. Seborrhea, seborrheic dermatitis,

acne rosacea, acne vulgaris and dermatomycosis responded well in most instances to colloidal sulphur, and as wet dressings in subacute eczema and dermatomycosis it had a certain value. He did not find the colloidal preparation to be of any appreciable value in the local treatment of psoriasis.

Sulphur is described as being insoluble in water, nearly insoluble in alcohol, slightly soluble in fat solvents and oils and freely soluble up to forty five per cent in carbon disulphide. This solution has an offensive odor that almost prohibits its use. No one, however, in so far as the literature reveals has described a sulphur in solution that is stable, bactericidal, isotonic with the blood, readily absorbed, of extremely low toxicity, and which may be employed intravenously in amounts large enough to be of therapeutic value, such as is the basis of the present presentation.

INTRAVENOUS ORGANIC SULPHUR

The intravenous use of sulphur as herein described is new. The solution is a clear, straw-yellow to amber colored liquid with a strong sulphur odor. It is stable, bactericidal and isotonic with the blood.

The chemical analysis of this complex substance is incomplete. The total sulphur analysis of the material averages 0.185 per cent by weight, and is distributed possibly as thirty per cent allyl sulphide, twenty five per cent polysulphide, thirty five per cent allyl mercaptan, seven per cent polymer (insoluble material), and possibly three per cent thio acid. Each cubic centimeter of the final solution contains approximately two milligrams of sulphur.

The material may be separated into three distinct fractions, namely, an ether extract, an ethyl acetate extract, and an insoluble portion. It is possible that one of these three portions contains the active constituent, which, if true, will simplify matters. This phase of the study is in progress, but as yet, nothing definite may be said.

The solution may be administered with safety by any route into the human organism, that is to say, intravenously, intramuscularly, intracutaneously, subcutaneously, orally, by inhalation in the form of a spray, and by inunction as

*From the Clinic of Dermatology and Syphilology of the Boston Dispensary.

Read at the Annual Meeting of the Massachusetts Medical Society, Section of Dermatology and Syphilology, June 2, 1934.

†Thurmon, Francis M.—Physician in-Chief, Clinic of Dermatology and Syphilology, The Boston Dispensary. For record and address of author see "This Week's Issue," page 310.

an ointment It is of extremely low toxicity

Experimentally, in the dog, Young³ has demonstrated that large amounts of the solution given intravenously produce a distinct pressor effect upon the parasympathetic system A similar effect has been observed clinically on four occasions in a single patient, an Italian male, aged forty-two years, who is receiving intravenous sulphur for dermatitis herpetiformis His reaction is characterized by bradycardia and mild air hunger, the heart rate slowing from a normal seventy-six beats per minute down to fifty-eight, the cardiac impulse being strong and of mechanical regularity This untoward reaction is quickly relieved by atropine sulphate grain 1/150 hypodermically, and is not nearly so alarming as the nitritoid reactions observed in arsphenamine treatment for syphilis

Its low toxicity is illustrated by the fact that fifty-eight patients with psoriasis have received a total of 1,337 intravenous injections (total 21,442 cc) of the preparation, each injection ranging from 5 cc to 25 cc over a period of the past eighteen months with only two patients manifesting untoward reactions of a major type Blood counts and examinations of the urine, repeatedly performed on patients during and following the sulphur intravenously, have thus far failed to reveal any abnormal change, except that occasionally patients will show a slight increase in the blood cell count and hemoglobin, the latter increasing from five to fifteen points, the white cells to a count ranging between 9,000 and 10,000, and the red cells, at times, increasing as much as 12 million per cubic millimeter when the count is below normal

The drug has been administered to patients without regard to age or sex, the youngest patient being an Italian boy, aged eight years, who, within sixteen weeks, received thirty intravenous injections totaling 337 cc, the oldest patient being an Irish male, aged seventy-three years, who received fifty-two injections in seven months, totaling 957 cc, each without ill effect

Of the fifty-eight patients treated there were the following conditions present in addition to psoriasis pregnancy, diabetes mellitus, alimentary glycosuria, biliary cirrhosis, infectious jaundice, postarsphenamine hepatitis, essential hypertension, cardiorenal disease, aortic dilatation and insufficiency, arteriosclerosis generalized, and orthostatic albuminuria The drug was administered to these patients and to two additional cases during the febrile period of erythema multiforme without untoward reaction Repeated examination of the optic fundi has failed to reveal a single toxic manifestation These facts indicate a low degree of toxicity

CLINICAL MATERIAL

During the past eighteen months eighty patients with psoriasis have been under observa-

tion, fifty-eight of whom received organic sulphur intravenously, and twenty-two were used as controls Of the fifty-eight patients treated, thirty-five were females and twenty-three were males These patients have had psoriasis for a total of 553 years, the shortest duration being seven days, the longest fifty-eight years, with an average duration of nine years Thirty-three of the cases had psoriasis ten years or longer previous to the beginning of this special type of treatment Of racial distribution there were Irish, American, English, French, Scotch, Canadian, Norwegian, Jewish, Italian, Lithuanian, Sicilian, Belgian and one American Negro

The psoriasis lesions were of the type and distribution generally described Six patients developed pustules within the plaques during the subacute stage of their eruption The scalp, nails and face were commonly involved, as well as the trunk and extremities Five patients had psoriatic papules on the soles and palms

The number of intravenous injections given was 1,337, total volume 21,442 cc, the average dose being fifteen cc The average treatment period was 9.6 weeks The longest observation and treatment period for a single case has been fourteen months, during which time the patient received 87 injections (total 1,512 cc) The psoriasis of this patient underwent complete involution, recurred during a four months' interim without treatment, and at present is well on the way toward involution

In all cases syphilis has been ruled out as an etiological factor by physical examination and negative blood Wassermann, Kahn and Hinton reactions

CLINICAL USE OF INTRAVENOUS ORGANIC SULPHUR FOR PSORIASIS

Intravenous organic sulphur has been found to be of value in the treatment of all types of psoriasis It is advisable to start each patient on treatment three times a week until ten or twelve injections have been administered For an adult, ten cc is the initial dose, the subsequent dosage ranging from fifteen cc to twenty-five cc, depending upon the response of the individual lesions From the beginning a bland ointment is used

R_x Boric acid 8 00
Aquaphor (Duke)
Lanolin aa q s ad 60 00
Sig Apply locally b i d

This ointment keeps the psoriatic scales soft and flexible, prevents and alleviates dryness, pruritus, and the irritation occasionally encountered in the thickened, roughened and fissured plaques It is without curative qualities in so far as the psoriasis is concerned, but does act as a lubricant Many of the patients prefer to use a bland oil locally instead of an ointment, their

preference running to olive oil, mineral oil, or one of the so-called antiseptic oils in common use on infants.

The first change noted after the initial two or three injections is that the psoriatic areas are transformed into a vivid pink to cherry red color. This color change is most noticeable in the smaller papules and at the periphery of the larger plaques. Pruritus, which occasionally is an annoying symptom, is usually controlled after one to four injections.

Within the first seven to ten days of treatment the individual lesions begin to show a color of clearing around their margins which is devoid of scales and presents a smooth pink refractive surface. The scales of the papules instead of being thick, adherent, silvery crusts that leave bleeding points after removal are by this time soft, thin, flexible, broken up surfaces that are easily removed and do not leave bleeding points when they are shed. At first there is a free generalized shedding of scales and the patient upon disrobing leaves the floor or rug sprinkled with this fine, white powder-like desquamation, but later, there is very little scaling.

The process of involution continues at a pace varying with the individual response of each patient, until the areas are devoid of scales but are present as smooth, soft, pink, thin flexible papular elevations. Finally the papules become erythematous macular areas, easily blanched with pressure and eventually disappear when involution is completed. No pigmentation or roughness of the skin remains to mark the site of previous involvement.

The larger plaques undergo involution in a manner similar to their disappearance either spontaneously or with other forms of treatment. These areas which may cover an entire abdomen, thigh, leg, back, or sacrum, first undergo a general desquamation, which is followed by a transformation of the thick adherent silvery scales to a softer, thinner and more flexible type of scale which is easily shed without discomfort to the patient. The larger plaques not only grow thinner generally, but also show islands of clearing within the body of the plaques which gradually spread peripherally, leaving a series of interrupted papules marking the periphery of the previous plaques. In time complete involution occurs, leaving the skin with a clear texture no different than that of the normal skin for that particular individual.

Needless to say the large thickened plaques are the last to disappear. Some patients may require as long as six to nine months to undergo complete involution of their psoriasis, but when one considers that these cases have been existent for many years, this period for recovery does not seem excessive and what is more im-

portant, intravenous treatment is not continuous throughout the entire interval.

Each of the patients was ambulatory and carried on his usual daily occupation without loss of time or inconvenience other than the necessity of attendance for injections.

Following the initial ten to twelve injections, which at the most covers the first month of treatment, the patients are either given a rest from injections for two to three weeks, or are continued on intravenous treatment at seven-day intervals for a total of sixteen to twenty injections. By this time, that is to say somewhere between the tenth to the twentieth injection those areas that have not disappeared, seem to reach a stationary period in their improvement, and further continuous treatment is of no avail. When this stage is encountered the intravenous injections are temporarily discontinued but the local applications are carried out for the succeeding three to four weeks then intravenous therapy is resumed and the areas again begin to involute as rapidly as at the inception of treatment for that particular case. Occasionally stubborn and resistant psoriasis is encountered which chrysarolin, crude coal tar and sunlight will not materially affect. In this series there have been two such patients, one a physician's wife, the other a student nurse. For a time these two patients responded well but eventually reached a period where further treatment ceased to be effective. Their psoriasis was improved but did not entirely clear up and with them it was deemed too much an effort for the value received to carry on further.

Psoriasis of the scalp responds rapidly to this type of therapy. Hot oil shampoos are advised once or twice weekly and the bland ointment is rubbed thoroughly into the areas each night before retiring. Within two to three weeks the thick, matted, crusted and scaling scalp is reduced to a smooth erythematous surface which soon disappears, and often the areas denuded of hair begin to regenerate a new growth of soft fine hair.

Psoriasis of the nails shows a varied response. When the nails are long thickened and disfigured, it is best to remove them. But for the ordinary psoriatic nail which is pitted, thickened and disfigured but which may be kept clipped proximal to the end of the finger or toe, the response is better. With this type even though the involvement extends up into the matrix or nail bed, often the process is arrested and as the new normal nail grows from the matrix the psoriatic portion is clipped at the distal end. Eventually in three to seven months new nails clear of psoriasis may be formed.

Recurrences. The eruption of psoriasis pursues a cycle: there is a stage of progression or active evolution, a stage of quiescence, and at times a stage of spontaneous involution, or re-

gression From time to time, we observe periods of progression or regression which, owing to our lack of knowledge, we are unable to explain. There is, of course, a stimulation to epithelial cell growth with each outbreak of psoriasis. There is no doubt that the epithelial cell growth impulse may be intensified or weakened by the intravenous use of the organic sulphur herein described. Active, inflammatory and progressive psoriasis that is spreading rapidly can readily be brought under control. Occasionally, during the course of treatment, new lesions will appear. If they are few in number, treatment is continued, but should their appearance be widespread and several areas be simultaneously involved, it is advisable to discontinue the injections for two to three weeks, then treatment may be resumed.

In two of the early cases of this type, where treatment was pushed, the areas became large, erythematous, maculopapular and confluent. When treatment was stopped they cleared leaving soft normal skin. In another similar case a dermatitis was superimposed upon this flaming spread of psoriasis. Recovery occurred in three weeks and was characterized by a general exfoliation of the skin, without loss of hair or nails, and otherwise uneventful.

Not a Cure Intravenous organic sulphur as herein described is not a cure for psoriasis. With proper administration of the drug it is possible to control psoriasis and to effect a complete involution of the eruption. Remissions have been attained that have lasted six months and these cases are still under constant observation. Other patients in whom complete involution of psoriasis has been accomplished have had recurrences in less than six months, but with additional treatment at the incipency of such a recurrence it is possible to render it completely under control.

The results attained by this method of treatment were superior to the usual procedures commonly applied in the twenty-two patients used as controls in this series. The control cases received dietary management, and local treatment such as the Alpine Sun Lamp, Cold Quartz Ultraviolet radiation, sunshine, and ointments of various kinds including chrysarobin, collosol chrysarobin, the tars, ammoniated mercury, salicylic acid, precipitated sulphur, and arsenic in the form of Fowler's solution orally and neoparsphenamine intravenously. Eighteen patients of the control series are still under treatment.

The more severe or extensive the psoriasis the more gratifying is the result attained with intravenous organic sulphur. For the mild case with only an occasional psoriatic area here and there, or an isolated plaque lying beneath an unexposed area, it is doubtful whether the intravenous therapy is merited, since the treatment occasionally requires too long a period in proportion to the value received. This type is

just as amenable to intravenous sulphur as the type with widespread lesions, but the continual repeated injections as contrasted with the lack of inconvenience of local therapy does not seem justified.

SUMMARY

1 An organic sulphur in solution has been described.

2 The technic of its administration and its use in fifty-eight patients with psoriasis has been described.

3 When administered intravenously the organic sulphur in solution has a decided and beneficial effect upon psoriasis.

DISCUSSION

CHAIRMAN WHITE. The discussion will be opened by Dr William J Macdonald of Boston.

DR WILLIAM J MACDONALD, Boston. *Mr Chairman and Fellows*—I think probably this contribution of Dr Thurmon's to the puzzle of psoriasis is well timed. I suppose amongst dermatologists who address society meetings the question of psoriasis never fails to come up. I think probably every time I address a meeting, somebody will come up and say, "Doctor, what do you know about psoriasis? Is there anything new?"

Well, dermatologists, in the past, and in the present too, have been very non committal on that point. This contribution of Dr Thurmon's is distinctly a step forward, because, although he very conservatively tells us he is not giving us a cure, he is giving us something worthwhile. I think the salient points of the paper are these: the ease and painlessness of treatment. Nobody likes injections either gluteally or subcutaneously. Less objection is expressed for the intravenous route. Where we have treatment which may be given intravenously, and which is non toxic and safe, at least we have something very worthwhile.

He also tells us two other very important points. First, as to psoriasis of the scalp. I suppose you will agree with me to-day that the hardest problem in psoriasis is the amelioration of the psoriatic lesions on the scalp. Girls will not put anything greasy on the scalp. Here Dr Thurmon tells us that intravenous organic sulphur is definitely, after a few doses, helpful to this condition. That is a very startling statement. I sincerely hope we will find that true. I hope the rest of us are going to have the same result.

Dr Thurmon's next statement is that it relieves the pruritus. Not all cases are pruritic, but at least a good number of them are. I congratulate Dr Thurmon upon telling us another drug with which we can meet and combat this horrible pruritus in psoriasis.

What else can be done for psoriasis? Fully 70 per cent of the audience are not dermatologists, and

they are here today not only to hear this paper but to learn what is good and what is inefficient. I think today the outstanding ointment is undoubtedly that drug about which Dr Stokes spoke at Cleveland dioxanthranol 1-8. It is put up in three strengths, and is marketed by Abbott & Co. As a local remedy today there is really nothing quite so efficient as anthralin ointment. It does pigment. It causes no marked dermatitis unless you get it very close to the eyes. I think allied with intravenous organic sulphur we can have two remedies going hand in hand.

I personally believe arsenic should be relegated to the limbo of the past. Patients will wander away and take it without your knowledge. I believe the x-ray should be given up although it is a splendid remedy for psoriasis. If given conservatively I think the ultraviolet light is useless in big psoriatic patches. It may be efficacious in small lesions and should not be discarded and is a safe resource.

Boiling it down today in the treatment of psoriasis we have Dr Thurmon's splendid contribution to this subject, allied with Dr Stokes' resurrection of this drug dioxanthranol 1-8. The only thing we have to take cognizance of is that this drug might be costly. I wonder how this will affect our private patients. They merit consideration as well as our clinic patients.

In concluding I want to thank you Dr Thurmon for the splendid paper and for the consistently hard work done on it.

CHAIRMAN WHITE Dr Bernard Appel will continue the discussion.

DR. BERNARD APPEL, Boston. The battle with this dragon of psoriasis is still on including dietary management and control of intestinal flora, preparations that kill fungi, vacuoles radiations of electrical or ery ointments and so on but we always come back to the department of chemistry with sulphur arsenic mercury and back to sulphur again. The atom of sulphur forms a very important part in the molecule of protein and therefore it is related to the biochemistry of the human body.

The general use of sulphur externally in psoriasis is only too well known, as is its relative ineffectiveness. But it is quite possible that we have here a form of sulphur which may be something new and something of great value. We know that the particular form of any element controls to a large extent its pharmacology. For instance arsenic, in the form of Fowler's solution, arsenophenine, and neoarsphenamine presents three different examples of pharmacodynamics. The use of sulphur in this particular form has been known to the arthritic clinic at the Boston City Hospital and although I am not authorized to quote the physicians in their procedures, I can say that they very kindly lent me some of their substance to use in psoriasis. My personal experience with this particular preparation is not extensive enough to enable me to form any opinion as to its therapeutic value, but I can corroborate Dr Thurmon's claims as to its relative harmlessness.

I think that any addition to our armamentarium in the treatment of psoriasis is welcomed by all of us. Those of us who have listened to the various new treatments of psoriasis as they arise are perhaps very justly skeptical, like the men who heard the boy cry "Wolf! wolf!" We cannot afford however to turn a deaf ear to anyone. We must continue to be grateful to anyone who continues to work this already well-harrowed field because he may turn up a gold nugget for us any day—or perhaps one of sulphur!

CHAIRMAN WHITE The paper is open for general discussion.

DR. H. M. LANDISMAN, Boston. I believe Dr Thurmon should be congratulated on the excellent work he has demonstrated today in the treatment of psoriasis. I have had a little experience with some cases of psoriasis in my private practice. I felt, after a careful study of the disease, that it was due to a mild disturbance of the gastrointestinal tract and with that in mind I treated a number of cases and I seem to have had some success with those that I was able to follow along. There were only a few I might say that I feel I did well with.

I will mention what the drugs were that I use. I begin with calomel and magnesium sulphate solution regulate the diet, and then use the following preparations. Internally tannalbin, ichthammol, iron salt, bismuth and salol, and Fowler's solution and externally ichthyol ointment and the Alpine Lamp.

My first treated case as above which did not recur was in 1918.

DR. ARTHUR M. GREENWOOD, Boston. I want to congratulate Dr Thurmon on the thoroughness and conservatism of his work. I think we have to take all these newer experimental remedies with reservations however. Looking back over the records we see so many reputed cures of a disease that is liable to recrudescence. So not disparaging him at all I think such work has to be carried over a longer period of time. I think that similar and fully as good as to results is the recent work of Dr Oliver and Dr Crawford. I cannot agree with Dr Macdonald as to the harmlessness of anthralin. I have seen fully as many cases of dermatitis in the 25/100 per cent strength as with chrysarobin.

DR. JOHN G. DOWNING, Boston. I enjoyed this paper exceedingly and I would not have risen, except because of Dr Greenwood's remarks regarding anthralin ointment, which I wish to second. I have just discharged a patient who has been confined to bed for three or four weeks after using anthralin ointment on the feet, for a fungus infection. He had a very severe dermatitis accompanied by marked swelling of both feet, with large bullae which contained a peculiar brownish yellow serum.

DR. E. LAWRENCE OLIVER, Boston. In regard to anthralin, we must realize that it is very closely related chemically to chrysarobin. Therefore there is no reason why we should not expect dermatitis in some individuals, even with very minute strengths. I think when anthralin is used it should not be started stronger than 1/20 of 1 per cent. I have seen 1/10 of 1 per cent cause quite a severe dermatitis. If we remember that anthralin is much stronger than chrysarobin we will use it with great care.

I wish to congratulate the reader of the paper on his excellent work, and hope that we will all get as satisfactory results as he.

DR. MACDONALD. About the possibility of dermatitis accruing from anthralin this is a disease that has to be treated rather strenuously. It will produce dermatitis in certain cases. I have had cases of my own of very remarkable dermatitis coming from anthralin, especially on the scalp. But what I want to make clear is this. Of all the local applications we have to-day I think it is the best. I think we ought to dilute the preparation that comes from Abbott with vaseline or cold cream and if the patient is intolerant to it give it up. As Dr Stokes himself says it is extremely harmless to the skin. He emphasized that it will cause very few reactions.

even around the eyes. You will find it described in a recent number of the *Journal of the American Medical Association*.

I am very sorry that Dr. Downing and Dr. Oliver have had such experiences. If they are willing to lessen the strength of the ointment, possibly they won't get such results in the future.

CHAIRMAN WHITE: Will Dr. Thurmon close the discussion?

DR. THURMON: In closing I wish to thank these gentlemen for their discussion. I do not believe

there is anything particular to add, other than what I have said, except that I think it is interesting that here is a sulphur preparation which may be given intravenously with safety, which is the first time that that has been accomplished, that is, in amounts appreciable to be of therapeutic value.

CHAIRMAN WHITE: The next paper is a discussion of "The Diagnosis of Industrial and Non-Industrial Skin Diseases" by Dr. John G. Downing.

Dr. Downing showed and commented on lantern slides during the address.

THE DIAGNOSIS OF INDUSTRIAL AND NON-INDUSTRIAL SKIN DISEASES*

BY JOHN G. DOWNING, M.D.†

THE skin, being the protective organ of the body, has suffered from trauma ever since man began to work, and references of injuries are found in the early ages. The first definite occupational dermatitis was described by E. Kaempfer in 1712, it was caused by lacquer varnish. Willan in 1798 reported skin diseases occurring among metal workers, grocers, bakers, and shoemakers, and since then, there has been a steady increase in literature on dermatoses due to industry.

The tremendous growth in industry has brought the workmen in contact with physical, chemical, and vital agencies which have introduced new hazards. The records of the Massachusetts Department of Labor and Industries show that forty new industrial poisonous chemicals were introduced in a single year. The figures of the Massachusetts Industrial Accident Board show that for the year ending June 30, 1933 there were 96,144 cases of injuries reported, of these, 31,769 lost more than one day from work. There were 410 disturbances of the skin. Two hundred and sixty-five industrial disease cases were investigated by industrial inspectors during the year ending November 30, 1934. An examination of these same data indicates that seventy per cent were diagnosed as dermatitis. Glazers, wheelmen and seasoners, who handle skins treated with chromic acid and other strong solutions in tanneries, claim thirty per cent of the total of 182 cases of dermatitis. Seventeen per cent of the total morbidity is associated with the wet finishers, color mixers, backtenders and dyers in textile mills, who come in contact with various dye, caustic and acid solutions. The next highest prevalence is found among shoe and shoe finding workers with eleven per cent of the cases, and among rubber goods workers with eight per cent of the cases. The remaining cases occurred in a rather broad industrial classification.¹

It is apparent that we do not have so many

skin injuries as other countries, for in England in 1927 Overton showed that of 1349 industrial cases, 979 (or 72 per cent) were skin infections.²

In New York for the year ending June 30, 1932, 653 cases of occupational diseases were reported to the State Department of Labor, of which, 230 were skin diseases, showing that one out of three cases applying for compensation was a cutaneous disorder.³

There are very few occupations which are exempt from occupational skin diseases for the causes of these eruptions are numerous and difficult to demonstrate, so that, it is essential to know the substances used and the various processes of the work in question. Frequently it is necessary to solicit the aid of the plant engineer to obtain definite facts regarding the physical and chemical backgrounds. The majority of these cases are fairly clear cut, and so, it is not difficult to diagnose and predict the course of the skin eruption. However, in doubtful cases, every possible angle must be considered, for with compensation as a verdict, in order to be just to the patient and the employers, one must avoid uncertainty and be able to differentiate an industrial and non-industrial skin disease. As soon as an eruption appears on the skin of most workers (whether banktellers or laborers), they immediately search for the cause in their work and, though the latter may be engaged in work where there are irritants present, one must not be too hasty in blaming the occupation for frequently there are just as many causes outside of the work. Then too, there are workers who, when told that the condition is due to their work, are just as positive that it is not. It is often difficult for the patient and the employer to understand why a substance, with which a man has been in contact for years without the slightest amount of trouble, can suddenly be the cause of a severe inflammatory disease of the skin, and it is almost impossible to convince them. However, the medical man with the knowledge of infectious diseases, serum reactions, and protein sensitivities, can readily understand this fact. Fortunately, only a small fraction of workers exposed to the

*Read at the Annual Meeting of the Massachusetts Medical Society, Section of Dermatology and Syphilology, June 3, 1935.

†Downing, John G.—Assistant Professor of Dermatology, Tufts College Medical School. For record and address of author see This Week's Issue, page 330.

same conditions in their occupations are affected by them, just as only a relatively few people are poisoned by ivy or other plants.

The majority of the eruptions due to occlusions come under the classification of *Dermatitis Venenata*, that class of inflammations which are produced by contact with external irritants whether of a solid, liquid, or gaseous nature and which may belong to the mineral, vegetable, or animal kingdom.

The loose use of various terms has led to more or less confusion, such as Contact or Artificial Dermatitis, Industrial or Occupational Dermatitis, and Trade Eczema. The loose use of the word eczema has been the most confusing. Formerly eczema covered a large group of skin eruptions whose etiology was unknown, but with the stimulus started by the search for the irritant in industrial eruptions, a great deal of knowledge has been obtained regarding this unknown quantity, in fact, the groundwork of the present knowledge of eczema was founded in this particular branch of medicine. Dore and Franklin⁴ define eczema as "an inflammatory condition of the skin originating without known external irritation and characterized in some stages of its evolution by serious exudation." Eczema and dermatitis are identical microscopically and macroscopically, however, in the latter, the source of irritation may be known and can be applied or withdrawn at will, it runs a definite course and begins to subside when the irritant is removed, lesions develop rapidly on the areas of contact showing a marked asymmetry and the severity depends on the strength of the irritant, the extent of the surface in contact, and the length of exposure, it can easily be reactivated by reapplying the irritant. Whereas, the condition we call eczema, arises spontaneously without any apparent cause, its distribution is not related to any external irritant but may affect all areas in succession or simultaneously it has no definite course and tends to recur frequently, probably due to some constitutional peculiarity. The words industrial dermatitis⁵ are more descriptive, in that they indicate the type of lesion and the causative factor.

Routine examination and frequent inspection of employees will reveal a beginning lesion which early treatment may abort (if they are instructed as to the value of the early detection of infections and impressed with their danger, they will report skin eruptions more frequently). In determining whether an eruption is industrial the history is of prime importance. Careful and repeated questioning of the patient is necessary not only in regard to his present work, but also his past occupations, and whether he has ever had any previous skin eruptions. History taking may be very difficult especially if the patient is a foreigner, the use of interpreters

is very unsatisfactory. The patient may know very little regarding the process of his work, and he may think that he is coming in contact with some substance which is not actually present. A visit to the factory or a talk with the plant engineer may be necessary for it is of the utmost importance to know these factors, note should be taken as to whether the process has been changed recently, or whether some new substance has been introduced, for we find more accidents in new industries than in old. The method of cleaning at home, or at work, is also important for here may be the causative factor, such as the effort to remove stains with strong alkalis.

The time of onset is important with regard to its relation to work days and holidays, and its progress at these times. The areas involved, and the order in which other parts were affected may be important clues. The patient's description of the beginning subjective symptoms such as pain, itching, etc., together with his description of the initial lesion are helpful hints for it may have started with a slight burn or cut to which aggravating treatment was applied, or the patient may have a slight bacterial or fungous infection similarly overtreated. It is also well to inquire regarding the patient's hobbies and pastimes. An outlined card containing various facts such as age, nationality, family and past history is helpful.

The entire surface of the skin (whether erupted or not) should be studied, experience discloses to the industrial physician whether the eruption is the type which usually appears after contact with the irritants used, for as a rule, industrial dermatoses, under the same conditions, produce fairly similar eruptions, so that, the lesions should be consistent with the history of exposure to certain irritants. He should know whether there are agents in the patient's work which would produce a dermatitis and which are active enough to further its spread. The location of the lesions is important for a dermatitis tends to remain limited to the areas of contact.

It is well to remember that the eruptions of industrial dermatoses may be almost as varied as those of syphilis. An industrial dermatitis usually starts as a brilliant redness or erythema with small vesicles which tend to remain discrete, they increase only as long as the irritant is present, exudation is not marked and when the cause is removed the vesicles and exudate begin to decrease. However, eruptions from an internal source may appear anywhere and show minute vesicles which rapidly form and coalesce with marked exudation, and which recur without apparent cause.

The time of onset may vary from a few hours to one or more weeks depending on the severity of the irritant the eruption may consist of merely an erythema plus edema these disap-

pear rapidly and the skin may simply desquamate. During the stage of edema, we get all types of wheals and papules, in severe cases vesicles and bullae appear. As a rule, these contain clear fluid except in plant poisoning, where they may be hemorrhagic, exudation then appears which later dries and there is the formation of crusts. After the vesicles and exudation dry, the skin becomes infiltrated and with the loss of elasticity, fissures appear along the lines of the joints, the skin then shows accentuation of the normal markings with scaling and pigmentation. A certain group of irritants such as oil and coal tar will produce a folliculitis with pustules.

With the cause revealed, prognosis is clear and the treatment obvious. In a true industrial dermatitis, you should have a fairly definite probable cause, it is easy to confuse these occupational skin disturbances with those due to a congenital or an acquired skin disease such as those from toxins, food allergies, and septic or mycotic organisms. The difficulty here is that they do not have a definite etiological factor such as syphilis, tuberculosis, or anthrax. Focal infections should be searched for, routine blood examinations are important. Fungous infections may precede a dermatitis due to external substances or a dermatitis may afford entrance to a subsequent fungous disease and while suffering from either, the patient may become more sensitive to other factors to which he was formerly immune.

There are substances which will produce the same result whether taken internally or applied externally, for example, quinine.

An important point to remember is that some people may react to a substance after only a few hours' contact, while others may be immune for years.

A useful method in the search for the suspected substance is the performance of patch tests. If the substance is a liquid, a piece of linen is soaked with the substance and this is placed in direct contact with the skin, if a dry substance is used, it should be applied dry and also moistened, it should be applied to the skin in the same manner and covered with an impermeable tissue held in place by an adhesive strip. The suspected substance should be allowed to remain in contact with the skin for twenty-four hours. In doubtful cases, it is a wise plan to use a normal skin for a control. Positive tests show themselves in redness, edema, papules, or vesicles appearing in a period of from twenty-four hours to a week or ten days, however, the interpretation of these tests is difficult for they are useful only in certain types of skin diseases and may show reactions which are not true positives. Then, too, a negative test does not necessarily exclude the occupation for the test cannot duplicate the influence of the workers' environment, for example, soap itself may show a negative test but when a man is exposed for

hours in front of a steaming vat of soap, he still can have an industrial dermatitis despite the result shown by the patch test. The tests are important also in an attempt to discover the external irritants outside of a man's work. Here the private physician has the advantage for he will have more cooperation from the patient. He can test him out with various substances such as shaving cream, hair tonic, and plants. This procedure is difficult for the industrial physician because the man seeking compensation is not apt to try to disprove his case.

Fungous diseases are frequently mistaken for occupational eruptions for only a few occupations can cause a direct fungous infection. The most difficult to differentiate are those secondary fungous eruptions which are known as epidermophytids and trichophytids especially when the patient shows vesicles only on the palms and fingers. However, the presence of an active focus elsewhere is fairly good evidence. Microscopic examination and cultures are of little value for the "ids" are generally sterile.

Despite the careful study of the work, patch tests, and laboratory aids, there still remains an undetermined group the etiology of which cannot be solved.

Outside of the fungous diseases, a differential diagnosis is fairly clear cut between dermatitis venenata and those diseases of internal origin such as erythema multiforme, urticaria, and pityriasis rosea. Impetigo and scabies are frequently found, and they are apt to be very confusing, especially the latter, in women patients who deny an eruption on any part of their body except the hands and forearms.

In industrial dermatitis cases, remove the cause and in the severe cases recovery will be hastened by prescribing rest in bed and applying a soothing compound. All cases will respond more rapidly if they are removed from all possible contact with the causative factor, but this removal may end the worker's return to that trade, for on his return to work, he may suffer a recurrence of his dermatitis. However, this susceptibility is not limited to persons who have had an industrial dermatitis, but is sometimes found in workers who have handled irritants for years with impunity, and after a lay-off or vacation, return to their occupation and promptly suffer a dermatitis simulating an anaphylactic reaction. If possible, continue the man at work for some seem to develop an immunity, however, a change of occupation may be necessary. The recovery from an industrial eruption depends to a great extent on the individual affected, it depends on the patient's cooperation in his treatment. Some believe that as long as they are not exposed to their trade, they can do work such as gardening and cementing at home. When cases become prolonged with repeated attacks, search should be made for irritants at home, secondary infection, systemic disease, a constitutional eczema, or malingering.

ing, for, with the irritant removed, and after allowing sufficient time for the occupational dermatitis to heal, the original irritant cannot be held wholly responsible. The problem of conscious or unconscious aggravation or continuance of the eruption is difficult to solve. One may be convinced that the patient is a malingerer, especially when a recently healed disturbance of the skin recurs, on the day of an Industrial Board hearing, worse than it has been since the onset, but it is impossible to prove it to the satisfaction of a third person.

Prevention is of supreme importance and the more or less universal use of gloves would prevent many injuries, hand contact, in some cases, could be replaced by machine labor. Instructions should be given to each employee regarding personal hygiene. Frequent inspection and examination of the employees cannot be overstressed. The workers should be able to remove the traces of their work with nonirritating cleansing solutions, they should have impressed on them the value of changing their clothing at the end of the day's work.

It is difficult to readjust a man who has been engaged in doing a certain job for years and it is in this group of patients who feel that they have lost their trade that we find a prolonged sequela of dermatitis factitia which may be hysterical or definite malingering.

DISCUSSION

CHAIRMAN WHITE. The room is large and wide so I am going to ask the discussors to come forward and face the audience. Dr. Lane will begin.

DR. C. GUY LANE, Boston. I was much interested in listening to this paper of Dr. Downing's, and I would like to emphasize numerous points in his paper if time permitted but I am going to emphasize only certain features with regard to diagnosis.

In the first place I think that any dermatitis limited to hands and arms alone should at least awaken suspicion of industrial causation. In other words I believe occupation as a factor should be included. It is important enough to put it as strongly as that.

Secondly I think that in a case referred for an opinion regarding industrial causation we should be absolutely sure we are dealing with an industrial dermatitis and not with lichen planus or erythema multiforme or fungus infection. We frequently find applicants claiming an occupational factor when some other non-industrial condition exists. As Dr.

Downing has already mentioned, just because an individual is working with a possible irritating factor that factor need not be causing the dermatitis. With a physician the antiseptics used may not be the cause of his particular dermatitis.

I am reminded in connection with these dermatitis cases and the matter of detection of them relatively early of a case I have seen recently—a man working as a hairdresser mostly waving with a very extensive eczema of both hands especially the right. He came in contact with the alkali used in the wave. This eczema was of ten years duration practically continuous, with a little relief at times when he had had vacations. He had had treatment five or six years ago by one physician who gave him a few doses of x-ray but told him inasmuch as the condition did not respond it was inadvisable for him to continue with the x-ray. Notwithstanding this patient went to another physician who gave him as the patient says five or six times that dose and in the course of three years he had approximately twenty-five or thirty x-ray treatments and now the man shows not only chronic eczema but the beginning of changes seen in x-ray dermatitis. Here, early detection and refusal to treat while the case was still going on would have avoided a long future of sad events for this particular patient. Early detection I consider extremely important.

Dr. Downing has emphasized very well the need for having certain standards in regard to the diagnosis of these cases. Criteria for diagnosis of industrial skin diseases. I think first we should have a definite history of exposure to something we know may cause the particular condition. Secondly the history of attacks upon exposure to this particular agent, especially if it is a dermatitis or eczema, and clearing up upon removal of that particular cause. Thirdly eruption in the patient consistent with this particular cause. We all realize the different type of eruption in keloid or radium-dermatitis from that in ordinary dermatitis or eczema. Fourthly there should be correct time relationship bearing in mind the recent work of Osborne of Detroit, showing there is a longer latent period between exposure and eruption than we have supposed. The incubation time in industrial dermatitis is relatively short, but in keloid or radium-dermatitis it is relatively long. Fifthly there should be the lack of history of exposure to agents which might cause a similar eruption outside the occupation.

With these points in mind we can make a more sure diagnosis of occupational skin disease.

In closing I wish to call attention to the matter of disability from occupational skin disease. That disability may be partial disability only temporary perhaps or permanent partial disability. On the other hand cases occur in which disability is total possibly temporary total disability followed by ability to return to work, or it may be permanent total disability disabling a man from permanent work in a serious surgical injury may do.

CHAIRMAN WHITE. The discussion will be continued by Dr. J. Harper Blaisdell.

DR. BLAISDELL, Boston. Mr. Chairman, *Felloes of the Section*—The story of industrial dermatitis is really a serial in three parts. The first part is the correct identification of the industrial dermatitis. The second is the successful treatment of it. The third is the restoration if possible, of the patient to his occupation.

Now under the identification of industrial diseases the most helpful step in recent years is the use of the patch test but the patch test cannot supplant experience and judgment on the part of the doctor and that doctor who has the inductive skill of a Sherlock Holmes will come more nearly

to evaluating his cases correctly than one who simply takes the word and very sparse history of the patient.

There are one or two things that possibly might be of interest under the question of correct identification. It has been my experience that a dermatitis, either primary or recurrent, which occurs on Monday or Tuesday, or forty-eight hours after a holiday, is more apt to have incidence in week end pleasantries than in the industry.

The second part, the successful treatment, is complicated today very greatly by two factors, first, by secondary fungus infections. The average horny-handed son of toil is generally not a victim of fungus infections while at work. But let his skin be broken by dermatitis, and a very large per cent will acquire fungus infection, which being a sequela of industrial dermatitis, exposes him to treatment extending over weeks and months, far beyond the loss which would have been incurred by the primary injury. The second factor, growing more and more prevalent, is the question of what I call minor malingering. Under different conditions of elapsing compensation, a great many men and women find they can prolong the dermatitis by trauma voluntarily applied by mild scratching, or scrubbing the hands with soap and water. Dr Downing has told what I have seen so many times, where a man up for a hearing for the stopping of his compensation, unquestionably produces by such means a dermatitis which will continue him on compensation. They are not dramatic malingering cases, but they are common, and other than a matter of opinion, are impossible of detection.

On the third point, restoration of the worker to his former occupation, I wish to speak a little more at length, because here is a problem of vast economic importance to the community at large, which in the last analysis pays the bill for all of us. It is a phase to which I think the doctors have, until now, paid very little attention for several reasons, ignorance on the part of the employee, ignorance on the part of the employer, and complaisance on the part of the insurance companies, that are only too glad to get the man off their list, and inability of the doctor to carry out simple suggestions when the man returns to work. As an example, I recently saw a woman, one of several hundred employees, who habitually used daily a common, ordinary, black electric tape to protect her fingers in light mechanical work in which she came in contact with sharp edges. This black electric tape was used in several thousands of yards by hundreds of employees without trouble, and yet she came in with acute dermatitis, which a patch test showed was due to the electric tape. Breaking down this tape, it was found to be composed of several forms of rubber, asphalt, resin, and barium sulphate. The material causing the trouble was the resin. She cleared up promptly under treatment, and in this instance it was easy to return to work, protecting her fingers with ordinary adhesive tape.

Another example was a man, a printer, with a large earning capacity. He was on the point of stopping after years of chronic dermatitis due to pigments. We used General Electric Hand Cream No. 406, which is a cream composed largely of soap and silicate. He was able to apply this material to his hands and arms and have no further dermatitis. The use of this particular cream is limited somewhat because it is soluble in water. But it can be used where a patient is coming in contact with many other types of liquid.

On the other hand there is the case of a shoe worker who by repeated tests over many years shows he is sensitive to the finished form of leather, as it is used in the shoes. That particular man has

been on compensation ten times. He is now on compensation, with his hands 100 per cent well, and sitting perfectly tight on \$18 a week, with the prospects of continuing that until his 500 weeks of disability are used up. At present there is no solution for that man that either the insurance company wants to work out, or that I have been able to.

CHAIRMAN WHITE This subject is open for discussion.

DR. WILLIAM J. MACDONALD, Boston The only thing I will cite, in congratulating the speakers, Dr Downing, Dr Blaisdell and Dr Lane, is this, just the evidence of one industrial case. I want to mention a very interesting case published by a dermatologist from another city. It was that of a man who had facial dermatitis which would not clear up. The dermatologist sent him south for a vacation, and the eruption completely disappeared. On return to his occupation it returned. He went away again, came back, and it reappeared. This time the dermatologist paid a visit to the man's home. His hobby was making bows and arrows. When he made them, he drew them like this (indicating). In this case it was dermatitis from the wood. Very often a visit to the patient's home will find the cause.

DR. B. THURBER GUILD, Boston I enjoyed the papers very much. There are one or two comments which I should like to make. The first concerns the procedure of which Dr Downing spoke. His patient was sensitive to bronze powder, I believe. If, as I assume, that was a metal sensitization it seems to me that wetting the powder would so dilute the perspiration that there would be less likelihood of obtaining a positive reaction on the skin.

When an allergen of this nature comes in contact with the skin the crude metal is converted by means of the perspiration into a chloride or sulphide salt which is soluble and therefore capable of irritating or sensitizing the cells of the skin. Water would so attenuate the salt that it might be too weak to cause a reaction, at least within a few hours' time.

Another point is that we should be very careful to differentiate a sensitive skin and sensitized skin. That, I believe, would help in the better classification of these conditions and in directing the investigation of the cause of the trouble.

The presence of resin in the electric tape was significant. In the cases of several patients who have shown a dermatitis following the application of ordinary zinc oxide adhesive plaster, I have patch tested them to zinc oxide ointment and to the resin supplied me by a large manufacturer of adhesive plaster. In these instances the resin was always shown to be the cause of the trouble and never the zinc oxide, though heretofore the latter has been considered the sensitizing agent. If the young lady who was sensitive to the electric tape was not influenced by the application of adhesive plaster, it would be interesting to me to know whether there was resin in that particular plaster.

CHAIRMAN WHITE Any further discussion? If not, will Dr Downing close?

DR. DOWNING I wish to thank the gentlemen for their kind discussion, and to elaborate on Dr Guild's. I think that point about applying the substance dry is very important, because there is no question in some cases that a dry substance can be either fixed by the water, or whatever is used as a diluent, so if a patient is working with a dry substance it is important to patch test with the dry material.

There was an interesting case of a girl who developed herpes simplex and shortness of breath from contact with a certain powder. The powder turned

out to be lycopodium. By keeping her away from the powder the symptoms disappeared. There was an instructive observation in that case not only were the patch tests negative, but a mild superficial scratch test was negative and when the scratch test was done by an allergist who scratched very deeply there

was a marked reaction. This girl was sensitive to the lycopodium.

CHAIRMAN WHITE. A final paper on "Fungus Diseases of the Skin" will be read by Dr. Arthur M. Greenwood.

FUNGUS DISEASES OF THE SKIN*

BY ARTHUR M. GREENWOOD, M.D.†

NEARLY 100 years have passed since fungi were recognized as a cause of skin disease, and it is twenty five years since the publication of "Les Teignes", Sabourand's classic work on the subject. My wish is to outline, in the time at my disposal, the accomplishments of these twenty five years in the morphology, etiology, biology and therapy of certain fungus diseases of the skin. It is manifestly impossible to give credit to all the workers in this field or to cover the mass of literature, and a survey such as this is necessarily a personal estimate of events and methods.

The first careful clinical study of a group of these cases was made by Djellaleddin Moukhtar in 1892¹, followed by Whitefield, Kanfmann, Wolff and Sabourand. In this country Ormsby and Mitchell² were the pioneers in an able article published in 1916, and it is a tribute to their work to see to-day how accurate their report was in the light of our present knowledge.

It is not possible to go into textbook details of clinical description. No new clinical varieties have been described since Dr. Charles J. White's description in 1919³, except for the recognition of the skin manifestations of infections by monilia, saccharomyces and cryptococci.

Knowledge of the bacterial and fungus flora of the normal skin is essential in studying its parasitic invaders. I have been unable to find any report of the finding of a known pathogenic hyphomycete on the normal skin and investigations undertaken with this object in view have been negative⁴.

Benham and Hopkins⁵ in 100 normal young adults recovered monilia albicans from the skin or nails in no cases. Other yeastlike organisms chiefly cryptococci and mycodermata were recovered in seventy two per cent. Greenbaum and Klauder⁶ found yeastlike organisms in thirty five or 150 normal skins investigated. None of these were monilia.

Concerning the bacterial inhabitants of the normal skin, staphylococci are probably present in all cases. Greenwood and Rockwood⁷ found them in 100 per cent of interdigital spaces of the feet in diabetics. Haxthausen⁸ found them in eighty five of ninety two cases of normal skin

Owing to the necessity for special bacteriologic technique to recover streptococci from the skin when staphylococci are also present the results of the usual cultural methods are of no value in judging as to whether streptococci are normal inhabitants of the skin. It is probable when they are present, and certainly when in any numbers, that they are of pathologic significance. It may be fairly concluded that pathogenic hyphomycetes, monilia albicans, and streptococci are not normal inhabitants of healthy skin and if present in skin lesions are of etiologic significance.

Yeastlike organisms such as cryptococci, being inhabitants of normal skin, may or may not be of etiologic significance when recovered from skin lesions. It has been proved that they are causal in certain cases^{10, 11} but their presence does not always imply pathogenicity.

Although we may become increasingly accurate in the diagnosis of fungus diseases of the skin from clinical appearances, the final recourse is to the laboratory. There is undoubtedly a tendency to attribute too many dermatoses to fungi without adequate investigation. Mitchell¹² has pertinently called attention to this tendency. As he states, dermatoses resembling epidermophytosis may be bacterial, mycotic or occupational and "fungi which are so few as to escape detection by the intensive efforts of an experienced technician are not capable of producing lesions of the type under discussion."

The laboratory procedure for the finding of fungi in epidermal scales is simple but the time and persistence necessary for a report of value are not ordinarily available to the busy unassisted physician, and hurried examinations by the inexperienced are valueless. A very recent advance in the laboratory investigation of these cases is the elaboration of a technique for staining fungi in epithelial scales by Swartz and Conant. This should materially add to the accuracy of our laboratory investigation of clinical material and has already been of great service in apparently proving that the much discussed "mosaic" fungus is not a fungus.

Looking back over twenty five years of mycological investigation of these pathogenic fungi, we are impressed by the thoroughness and accuracy of Sabourand's original work. From the clinical standpoint, little if any, change has been made by investigators since the date of publication of "Les Teignes" and it becomes

*Read at the Annual Meeting of the Massachusetts Medical Society, Section of Dermatology and Syphilology, June 3, 1918.

†Greenwood, Arthur M.—Dermatologist, Massachusetts General Hospital. For record and address of author see "This Week's Issue," page 319.

increasingly evident that the linkage of specific clinical manifestations with specific fungi, except in the most general way, is probably impossible and perhaps unimportant. There is, however, a geographical distribution of species and varieties with some corresponding variations in pathogenicity which is to be worked out as influencing therapy. For instance, the *Microsporum* of the Pacific Coast are apparently distinctly less difficult to eradicate than in this vicinity, and corresponding differences may be found in the species of *Trichophyton*s.

Determination of the specific infecting fungus in any given case is important in considering therapy. Lewis¹³ has shown that ringworm infections of the scalp caused by *Microsporum lanosum* can be cured by local measures alone and that the more radical and difficult treatment by x-ray is not necessary in such cases. Infections by *Microsporum Audouini* are not curable by local treatment and require x-ray epilation. It has been my experience that infections with *Epidermophyton* are easier to cure than the cases in which the infecting fungus is *Trichophyton Interdigitale*, and the finding of *Monilia Albicans* in a lesion adds distinctly to its seriousness as well as suggesting the co-existence of a deficiency disease. These are problems for the clinical mycologist and can be worked out when accurate clinical and mycological reports on the pathogenic fungus flora of different sections of the country are available. Davidson and Gregory¹⁴ have reported a list of fungi infecting man in Manitoba, and this procedure should be followed by workers in this line in all sections of the country. Further investigation of the species and varieties of the pathogenic fungi is for the trained mycologist, a difficult task and not practicable for the clinician untrained in mycological research and unfamiliar with the intricacies of mycological classification, and such a mycologist should be on the staff of every large hospital and medical school. The marked variation of species of fungi under differing conditions of growth has led to the naming of many unjustified species, and several attempts at simplification of classification have been made in recent years. Of these, the most recent by Emmons¹⁵ appears to me the most reasonable. It is probable that many species thought to have distinctive cultural appearances and producing characteristic organs in culture are only varieties formed by differing conditions of growth. It has been shown by Emmons¹⁶ that one species may pass through a number of changes of color in culture and may from time to time produce organs thought to be characteristic of other species. He believes that certain "species" are varieties of one variable species. It seems to me that a classification such as Emmons proposes would do much to simplify a confused situation, especially in the taking and collating of a fungus census of the country.

BIOLOGIC INVESTIGATIONS

Plato and Truffi first demonstrated that an organism affected with trichophytosis and a healthy one reacted differently to the injection of a filtrate of a culture of the infecting organism. Bloch¹⁷ established the laws of biologic reactions in such cases. His researches showed that deep trichophytosis was not solely a cutaneous affection. It brought about alterations in the whole skin and sometimes in the internal organs, this was shown by an increase in leucocytes, swelling of glands, and sometimes of the spleen.

The biologic character of these changes was shown by the reaction of the patient to subcutaneous or intradermal injections of trichophytin and is analogous to the tuberculin reaction. It is more intense as the infection is more intense, is very slight for superficial trichophytosis, and practically nil for microsporiasis. It is not specific to each variety of organism but common to groups, each of these groups having its own endotoxin.

Sensitization may last years after the attack. Bloch thought that the sensitization was not humoral, that it was attached to the cells of the skin and that passive transfer was not possible. This has since been disproved. He held that the inflammation in the sensitized areas was a favorable reaction designed to counteract the invading fungi, possibly by the destruction or immobilization of their toxins or by the elimination of the focus, and that, just as in syphilis, there was a definite relationship between the degree of inflammation, the strength of the allergy, the number of organisms and the evolution of the disease. This he considered as illustrated by microsporiasis and onychomycosis which last long and show great numbers of fungi because their localization produces a minimum of allergy.

The study of hypersensitiveness led to the creation of a new group of dermatoses, the Trichophytids. Jadassohn and his school in 1911 called attention to these manifestations. It was found that after intracardial injections of spores into animals an eruption of disseminated papules appeared, these developed differently according to whether the animal was normal or had been sensitized by a previous fungus infection. The eruption appeared as one of five types: Lichenoid, scarlatiniform, pustular, nodular like erythema nodosum or polymorphic like erythema multiforme.

Bloch thought that the variety of fungus was not important but that it had to be capable of setting up a deep trichophytosis. This, however, has since been shown not to be necessary. For the production of Trichophytids a considerable degree of hypersensitiveness is necessary and this occurs late in the infection. Bloch also

demonstrated that the hypersensitiveness was greater near the focus of infection. He was in doubt as to what factor brought on the allergic reaction when it came in contact with the sensitized skin toxin, fungus element in the blood stream, or fungus element from without. A similar question arises in tuberculous, in syphilis it is known to be the spirillum. It seems practically certain that any of the three toxins, or fungus elements from within or without may act as the antigens.

Since Bloch's investigation the whole subject has been developed by various workers. Williams¹⁸ in 1925 from clinical observations deduced the occurrence of allergic eruptions with epidermophytosis of the glabrous skin and proposed the name Dermatophytid to include both these and the Trichophytids known to occur with the deep ringworm infections.

Investigations by W. Jadassohn¹⁹ Salzberger²⁰, and Peck²¹ have verified the accuracy of this hypothesis. It has also been proved that Trichophytin sensitiveness can be demonstrated by contact tests, producing an eruption of an eczematous type²², and that urticaria, hay fever and asthma may be manifestations of hypersensitiveness to fungus toxins^{23, 24}.

It may therefore be accepted as proved that a primary infection with pathogenic fungi either deep or superficial, sensitizes the cells of the skin, and the subsequent dissemination of toxins or fungus elements may produce secondary reactions, generalized or localized near to or distant from the original focus, which manifest themselves either as dermatophytids, as eczema, as urticaria, asthma or hay fever.

From the point of view of this summary we are most interested in the dermatophytids since they have been evoked to explain a dermatosis which has given no little trouble to dermatologists, the palmar and digital vesicular eruptions, persistent and recurring, which clinically suggest fungus origins but in which fungi cannot be found even after the most careful and persistent laboratory search. According to Williams' hypothesis these are allergic reactions in which the negative microscopic findings are to be expected. This view has ample support, especially by Peck's experimental reproduction of the entire chain of reactions in the human subject¹⁸. The validity of this conception of palmar and digital dermatophytids has been questioned by Scholz²⁵, and Tolmach and Tranh²⁶ in a discussion of the results of a series of their own observations concluded that the diagnosis of dermatophytid in many cases was unwarranted. It seems to me that we must admit the occurrence of dyshidrotic and eczematous eruptions of the palms and fingers produced at times by actual invasion of these areas by pathogenic fungi and at times appearing as an allergic reaction. Whether, in addition to these, there is a true dyshidrosis having no rela-

tion to either of the above causes is not, as yet, established and it must of course be admitted that there are many cases of eczematous eruptions in these areas which have no connection with pathogenic fungi.

In recent years the importance of fungus infections in relation to industrial disability and compensation has been recognized and many questions difficult of solution have arisen in this connection. In general it is now held that a primary fungus infection is not compensable unless its source can be proved to be a contact in the industrial plant concerned and that chronic recurring mycotic dermatitis aggravated by heat and moisture is not compensable, it being considered a condition common to all existence and to all industry. When, however, an industrial dermatitis predisposes to the spread or exacerbation of a chronic mycotic infection or when a mycotic infection immediately follows an industrial dermatitis it is held to be compensable on the basis that it is a sequel of a condition arising from the worker's employment^{27, 28}. Obviously the most painstaking investigation devolves upon those of us who would undertake to decide these questions with fairness.

The limits of a paper such as this necessitate a very brief and inadequate consideration of an important and interesting group of fungus infections, those caused by yeastlike organisms. Langenbeck in 1839 first described a fungus as the causal organism of thrush. It was later named *Oidium albicans*, and is now known as *Monilia albicans*. It is in recent years that careful investigation of this group of fungi has been taken up and its importance appreciated. The difficulties involved in the mycological study of this group and the impossibility of their accurate identification and classification without complicated laboratory procedures has led, as in the other pathogenic fungi, to a confusing multiplicity of varieties and names. This situation has, in recent years, been much simplified by various workers, in this country notably Benham, and Stovall and Bnholz, using as criteria in addition to cultural appearances, fermentation, agglutination and agglutinin absorption reactions.

The skin pathogens in this group known at the present, pretty generally fall into three groups: the monilia, saccaromyces and cryptococci. Of the monilia, one, *Monilia albicans*, is by far the most important. It is known to be the causal organism in thrush, and the thrush like infections of the mouth seen in pernicious anemia and other deficiency diseases, of infections of the vaginal mucous membrane and surrounding skin seen in diabetes and in pregnant women of limited or extensive infections of the glabrous skin, from comparatively transient intertrigos to extended and even fatal infections, of perleche, onychia and paronychia. Elsewhere than the skin it may infect the

bronchi and lungs and is a constant inhabitant of the intestinal tract in sprue, although not its cause. It has never been proved to exist as a saprophyte on normal skin but may live thus in the intestinal canal. It is particularly resistant to treatment in most instances and this resistance may be, and probably is, due to the failure to remove the underlying condition of the host which makes the monilia infection possible, whether it be a deficiency, glycosuria or some other factors of which we are ignorant. I believe the presence of a monilia infection always necessitates the consideration of factors outside the presenting dermatologic picture.

The two other groups, *saccharomyces* and *cryptococci*, are of less serious import as far as our present knowledge goes, but nevertheless often difficult of cure. Their presence in a skin lesion does not necessarily imply pathogenicity, since, as mentioned elsewhere, they may live as saprophytes on the skin. They have been found, assumed to be and in certain cases proved to be the cause of intertrigo, *perlèche*, paronychia, lesions of the nails, certain eczemas, and a very troublesome condition of the glabrous skin, *cryptococcosis epidermica*, described by White and Swartz²⁹.

In 1928 MacLeod and Dowling³⁰ published investigations which appeared to prove that seborrheic dermatitis of all types was a pure fungus infection with the *Pityrosporon* of Malassez. Recent work in this country on the same subject, I believe, is confirmatory but not yet published. It is an important addition to our knowledge of fungus diseases and suggestive in the further investigation of psoriasis which we so often see developing from an apparent seborrheic dermatitis. There is no known successful specific treatment for these groups of organisms and their therapy will be considered under the general treatment of fungus infections.

THErapy

The results of treatment of fungus infections of the skin are not, as a whole, therapeutic triumphs, and it is quite generally agreed by the most experienced that very few cases are ever permanently cured. It is a fact, however, that the great majority of cases tend to get well themselves provided that conditions unfavorable to the growth of the fungi are provided and that irritating "cures" are not used. It is our duty to make this clear to our patients, and while not underestimating the seriousness of certain types of the infection, we should not so overwhelm them with details of treatment and prophylaxis as to drive them straight to the druggist where they are sold a package of some proprietary remedy which is either so strong as to set up a dermatitis more incapacitating than the original infection, or so inert as to have no effect whatever. If the patient is fortunate, he will

get one of the inert preparations. If he is unlucky, he will use one of the proprietary high explosives and will have, in addition to his original infection, a dermatitis venenata and possibly a generalized allergic reaction. I think the members of this section will agree that many of our office and hospital cases are of this variety.

Of fundamental importance in considering therapy and prophylaxis are the facts that fungi grow best in epithelial structures and epithelial debris in the presence of heat and moisture and darkness, and that cleanliness, the avoidance of heat and the production of dryness are essential and basic factors in therapy.

Another consideration to be emphasized is that we should differentiate in our treatment the areas of actual fungus invasion and the manifestations of allergy. The failure to do this is a frequent cause of therapeutic disaster, for it is obvious that the application of an active fungicide to an area of allergic reaction will only make matters worse. If we are unable to differentiate the two conditions it is much better to treat neither with fungicidal substances. We have to consider that reactions of resistance and immunity in most of these cases do not take place in amounts sufficient to be of therapeutic value since most fungus infections occur in the uppermost skin layers where the fungi do not come in contact with living allergic tissue. We should consider that any condition, internal or external, leading to increased perspiration, favors the growth of fungi. Increased sugar concentration in the skin has been held to favor fungus growth, but except for the tendency toward yeast infections around the genitalia in glycosuria, I know of no proof of this assertion. Fungus infection of the feet in diabetics, while not more frequent, is more serious than in non-diabetics, because of the opportunity it offers for secondary infections.

Two fundamentals of treatment should be (1) The elimination of factors favoring fungus growth such as the prolonged maceration of the skin by the wearing of and exercising in wool socks, heavy boots, heavy gloves, heavy wool underwear and athletic supporters, (2) the avoidance of too active applications to the actual infected areas and the use of bland substances on the allergic reactions.

In general, three types of cases present themselves. (1) The acute vesiculopustular. On the hands or feet this type is best treated by soaks and wet dressings, either of liquor *aluminum acetatis* 1:16, potassium permanganate 1:2,000 or weaker, metaphen 1:3,000, or boric acid, four per cent. If the pustular element is prominent a chlorinated solution is valuable. This is carried out during the day, and boric ointment or an ointment of salicylic acid and sulphur two to six per cent in vaseline, or a borated dusting powder with ten to twenty per

cent tannic acid added is used at night. It has not been my practice to use x ray in any dosage in the acute cases although it has been recommended. I believe the risks of medico-legal complications are too great to compensate for any possible gain in this variety which is so liable to prolonged and explosive exacerbations, for which the use of x ray is certain to be held responsible. Neither strong Whitfield's ointment nor any of the proprietary modifications of his formula should be used, not only on account of the danger of dermatitis, but also because a violent attack on this type of the disease is likely to produce a generalized allergic reaction.

(2) The subacute type, either vesicular or macerated, and (3) the chronic varieties I believe in the long run are best treated by anphur and salicylic acid ointment, six per cent strength in vaseline, or by Whitfield's original formula

Acid Benzolic	57	xxv
Acid Salicylic	57	xv
Paraffin mollis	3	li
Oil Coccol nuciferae	ad	§ i

Either of these ointments may have added one per cent of thymol. Certain cases do well with Castellani's carbol-fuchsin paint, or other dyes. Iodine in one per cent alcoholic solution or as in Strickler's formula,

Iodine Crystals	1.3
Potassium Iodide	1.9
Acid Salicylic	1.9
Boric acid	3.9
Alcohol 50%	ad 60.0

is at times effective but in view of its proved fungicidal value¹¹ in vitro its use has been disappointing and seems to prove the difference in action of many substances when the human skin is substituted for the test tube.

X ray, in the subacute and chronic cases, is of distinct value used in fractional doses, having in mind its limitations and dangers. Used as a palliative measure and often giving great temporary relief, it should never be forgotten that patients who "shop around" are certain in the end to get sufficient radiation to produce permanent damage to the skin exposed. We should never x ray patients without ascertaining the amount of previous radiation they may have received.

The use of trichophytin in my experience has been of no demonstrable value in any series of cases. It may be that newer methods of preparing the trichophytin¹² and its use in higher dilutions as recommended by Templeton¹³ will give better and more consistent results.

I have had comparatively little experience with the use of inhalations of ethyl iodide as perfected by Swartz. Theoretically it should be useful in the recurring allergic manifestations caused by fungus elements brought by the general circulation to the sensitized skin and

in massive actual infections. Probably its use is not for the inexperienced, nor in the general run of unselected cases.

I have named but a few of the multitudinous preparations and substances used in the treatment of epidermophytosis and I do not at all mean or wish that what has been said concerning therapeutics should be taken as a counsel of despair. I have only meant to point out that as in so many therapeutic procedures there is an art in the use of a few well tried remedies, and that having in mind their limitations and powers, and knowing as well as possible in the present state of our knowledge what we are treating and what we may expect to accomplish, the results are, in a great majority of cases, excellent. What seems to controvert this statement is not so much poor results in treating the presenting case as the undoubted frequency of re-infections.

This brings us to the important subject of prophylaxis. Several facts are pertinent in considering reinfection. First, in most cases no immunity seems to be conferred by a previous attack of fungus infection. Secondly, fungi can grow on practically all the fabrics and materials which we wear. Thirdly, fungi can grow on the hair and epithelial debris, and the algal and bacterial slime which may accumulate on and in the cracks of wooden, cement, brick and tile floors.¹⁴ Fourthly, the addition of our generation to the frequenting of gymnasiums, baths and locker rooms where ideal conditions for the growth of fungi obtain, and the tendency of the generation to exercise violently and perspiring in unsterilizable socks and body clothing. It would be interesting to know whether the Romans, whose bathing habits were almost as unbridled as ours, were similarly afflicted with epidermophytosis. Fifthly, we have to consider the rather general indifference to the importance of the subject by health authorities and by those having in charge public baths, gymnasiums and locker rooms. This indifference is becoming less noticeable, and more and more prophylactic measures are being used with a distinct diminution in the number of infections where such measures are properly carried out. Sixthly, of considerable importance is the incomplete disinfection of most clothing by standard laundry procedures. Bonar and Dreyer¹⁵ showed that the fungicidal action of standard laundry practice at that time (1932) was effective for white cotton fabrics but doubtful for woolen and colored materials, and that the use of standard dry cleaning solvents on fungi in fabric had a negligible killing action in exposures of one to two hours. Articles ironed and pressed in laundries are subjected to a temperature of approximately 160°C (320°F), which is well above the thermal death point for the usual pathogenic fungi.

Prophylactic procedures in public sources of infection should consist in some such compulsory foothold as that advocated by Osborne and

Hitchcock³⁶, a one per cent solution of sodium hypochlorite changed every two days. This seems to have been effective where used, although as an actual fungicide this solution has to be in contact with infective material much longer than occurs in a footbath as used in baths and gymnasiums³⁶. Floors of showers should be scrubbed daily with soap powder, as mere flushing with water is ineffective. Shower baths are active sources of infection and every precaution should be taken to prevent or remove the algal and bacterial slime which accumulates on their floors. More cases of infection were found in a group of nurses occupying a dormitory with showers than in a similar group using tubs only (Massachusetts General Hospital). The most effective preventive against foot infection in baths and locker-rooms is the wearing of unlined rubber bathing shoes. It is a very safe rule never to walk barefoot on any flooring or floor covering. We cannot bring about the wearing entirely of white cotton material but it is definitely the safest material to wear next the skin, and there is no reason why sterilizable cotton socks cannot be worn next the feet, especially if they are to be subjected to heat and moisture and dirt. Perhaps most important in prophylaxis is the meticulous cleanliness of the feet, flexures and folds of the skin, with careful drying after washing and the use of dusting powder.

We have reached the end of this discussion but not the conclusion of the subject. We, as dermatologists, cannot accept the present situation in regard to fungus diseases as even approaching solution, and it is our problem to carry this study to a point where definite and specific therapy is possible.

DISCUSSION

DR. ARTHUR M. GREENWOOD, Boston. I appreciate the opportunity to present a paper at the opening of this most recent chapter of New England Dermatology.

I have reached the end of this discussion, but not the conclusion of the subject. I believe that we as dermatologists cannot accept the present situation in regard to fungus diseases as even approaching solution and I think it is our function to carry this subject to a point where definite and specific therapy is possible.

CHAIRMAN WHITE. Before calling on the discussers of this excellent paper, I wish to remind them of the by-laws that no one must exceed five minutes.

DR. JACOB H. SWARTZ, Boston. Mr. Chairman and Members of the Section on Dermatology—I am very

grateful for the privilege to discuss so excellent and complete a summary of Fungi Pathogenic to Man. I really have nothing to add but I shall attempt to emphasize a few of the points brought out by the speaker.

1 The importance of correct diagnosis. I remember not so long ago when even the most experienced dermatologist hesitated to make a clinical diagnosis of fungus infection of the skin without a microscopic and cultural checkup. Today the pendulum has swung in the other direction the clinical diagnosis of fungus infection is made freely without microscopic checkup thus making the statistics on the instances of fungus infection unreliable. Even with direct microscopic examination one is apt to err because of the numerous artefacts which simulate budding yeast cells or even branching hyphae which can easily be mistaken for fungi.

Dr Greenwood has mentioned a stain which has been recently developed by Dr Conant and me. The purpose of this stain is to make possible a more correct microscopic diagnosis by eliminating some of the artefacts I have just mentioned particularly the elimination of the mosaic like structures which are still interpreted by some as fungi. The technique of the stain is simple. It takes only a few moments longer than the accepted potassium hydroxide method and is as follows: the scale to be examined is treated with 5 per cent potassium hydroxide and then immersed in water for two to three minutes to wash out the potassium hydroxide. The scale is placed on a slide and a drop of lactophenol cotton blue is added and a cover slip pressed on the preparation. The preparation is slightly heated. In the case of a thick preparation or nail material after washing out the potassium hydroxide it is stained with a 1 per cent alcoholic solution of cotton blue and then mounted in clear lactophenol. The epidermal cells are stained light blue while the protoplasm of the hyphae is stained a dark blue. This particular stain is an advantage for teaching purposes and will, probably turn out to be the method for making permanent preparations.

2 The importance of the identification of the species. Dr Greenwood has mentioned that tinea capitis caused by the *Microsporum Audouinii* is more resistant to treatment than that which is caused by *Microsporum lanosum*. He has also mentioned that epidermophytosis that is caused by the trichophyton family is more resistant to treatment than that caused by the epidermophyton family. He also mentioned that the yeast organisms as a group particularly the monilia albicans and the cryptococcus are more resistant to therapy than the ring worm family. I fully agree with him.

3 A word about ethyl iodide inhalations in the treatment of fungus infections. It is not a panacea for fungus infections but is very helpful when intelligently used, particularly in the severe cases and in cases which are accompanied by an allergic manifestation, that is, an idea.

4 In closing I wish to make a plea for a mycological department in the medical school and hospital. Medical mycology at present is in a clinical end it is only through the cooperation of the clinician and the medical mycologist that this very important field will be simplified and made useful to all branches of medicine.

CHAIRMAN WHITE: Dr Ethel M. Rockwood. It is very pleasant to see a lady on the program.

Dr. Rockwood Boston. It may be of interest to give you an idea of the frequency with which we have isolated the fungi most common in this section of the country.

In scalp infections *Microsporum lanosum* occurred nearly three times as frequently as other fungi and four times as often as *Microsporum Audouinii* which is essentially an institutional infection.

Of the glabrous skin *Microsporum lanosum* occurred twice as often as the other dermatophytes.

In foot infections *Trichophyton interdigitale* was four and one-half times as common as epidermophyton and also four and one-half times as all other fungi.

In groin lesions epidermophyton was cultured three times as often as other fungi, but, in groin lesions as a whole epidermophyton occurred in only one-third of cases cultured or one out of every three and one-half cases, the others giving a growth of *Staphylococcus aureus albus* or citreus and a very occasional *Monilia albicans*.

Microsporum Fulyum heretofore considered as an infrequent invader has been isolated four times. *Trichophyton purpureum* and *Trichophyton* of the gypsum and niveum groups have also been recovered.

Cultures from chronic paronychia have yielded *Monilia albicans* more than six times as often as other yeast like organisms.

Isolations from the intertriginous areas have yielded yeast organisms so infrequently and pure culture of *Staphylococcus aureus albus* and citreus so consistently on repeated examination that it is suggestive that these latter may play other than a saprophytic rôle.

CHAIRMAN WHITE: The paper is open for general discussion. This is a very wide very important question. Somebody should say something or ask something.

Dr. Guild: I hesitate to inject myself twice into a dermatological meeting.

CHAIRMAN WHITE: Quite all right.

Dr. Guild: I would like to suggest that other sensitizations may easily follow in the wake of a primary fungus infection. Both Dr. Downing and Dr. Blaisdell state that fungus infection more easily affects a skin primarily sensitized by trauma. It is also true that a skin affected by fungus infection more easily acquires sensitization to other substances dyes, metals, fabrics or what not. One may be continuing the treatment of a fungus infection (or sensitization) when that allergen has ceased to be the cause of dermatitis and the real cause is some unsuspected material of quite a different nature.

CHAIRMAN WHITE: Any further discussion? Dr. Greenwood will you close?

Dr. Greenwood: I have nothing special to add except to emphasize what I barely mentioned in my paper and what Dr. Swartz did emphasize the importance of having a trained mycologist attached to our hospitals and medical schools. It is an extremely technical job and one which would be useful not only to us dermatologists but to the mycologists also. I hope that all of us who have any influence will use it to bring this condition about.

CHAIRMAN WHITE: Ladies and Gentlemen—We have come to the end of our program and the Chair wishes to thank the readers for their valuable and interesting papers and for the discussions thereon.

At the beginning of the meeting this section elected as Chairman and Secretary for next year Dr. Harvey P. Towle as Chairman and Dr. Jacoby as Secretary. Unfortunately I have this telegram from Dr. Towle "Sorry to miss the meeting. Sent to bed for the day."

The Chairman will ask Dr Jacoby to take the chair and close the meeting

CHAIRMAN JACOBY I thank you for this honor and privilege Is there any further business to come before this meeting?

DR LANE *Mr Chairman*—I wish to move a vote

of thanks for the retiring officers and a vote for their courtesy in this first meeting of the section

VOICES Second the motion

(The motion was put and carried The section meeting closed)

REPORT OF A FATAL CASE OF FLUORIDE POISONING*

BY LEO MALETZ, M D †

A FATAL case of sodium fluoride poisoning was recently observed at the Danvers State Hospital In view of the fact that fluoride poisoning is so infrequently reported it would seem opportune to report this case with a general summary of the subject

The first cases were reported in 1889 by Baldwin¹, an American chemist, who gave an excellent description of fourteen cases, one of which was fatal In 1911 Hickey² reported a fatal case in a ten-year old girl In 1915 Stanton and Kahn³ reported the case of an infant, nineteen months old, who recovered In 1920 Kockel and Zimmermann⁴ described two fatal cases In the same year Vallée⁵ reported seven cases with recovery In 1923 several authors reported cases, McNally⁶ described four deaths due to sodium fluoride with a review of the literature Sommelet⁷ reported two cases of fluosilicate poisoning, of which one was fatal Kurtzahn⁸ also reported a case of fluosilicate poisoning which was fatal Heinz and Haas⁹ reported one fatal case of sodium fluoride poisoning in that same year In 1924 Bizot¹⁰ reported a fatal case Lührig^{11, 12} reported two cases of fluosilicate poisoning in 1924 and 1925, both of which were fatal In 1925 Dyrenfurth and Kipper¹³ reported a single fatal case In 1928 Marcovitch¹⁴ reported a fatal case of fluosilicate poisoning Fullerton¹⁵ in 1930 described a single fatal case In 1933 Sharkey and Simpson¹⁶ described eight cases with one fatality They also made an excellent review of the literature, reporting in all, forty-one cases

In the state of Massachusetts there have only been two cases thus far reported, those of Hickey in 1911 and Fullerton in 1930 The reports of the Chief Medical Examiner of the City of New York (citing Sharkey and Simpson) contain records of eighteen fatal cases in the period of 1918 to 1930 In commenting on the comparative infrequency of this condition, we find that the files of the U S Public Health Service contain no records of previous cases

Contributions to the study of the toxicology of fluorides and alkaline fluoro-silicates were made by Janaud¹⁷ in 1923 Floyd DeEds¹⁸ in

1933 presented an intensive study of the entire subject of fluoride poisoning with special emphasis on chronic poisoning In the same year McClure¹⁹ described the physiological effects of fluorine

In all we have been able to find reports of fifty-nine cases of sodium fluoride and six cases of silicofluoride poisoning, of which total fifty-five per cent were fatal

Sodium fluoride is used most commonly in insecticides and is a common constituent of roach powder It is frequently dispensed in containers similar to those used for saline laxatives or baking powders Insecticides containing sodium fluoride are commonly stored in medicine cabinets or on the kitchen shelf This substance has also been mistaken for powdered sugar and flour Most of the cases reported were accidental

Sodium silicofluoride has a greater toxicity than sodium fluoride although the mechanism of the toxicity is the same, being due to the common fluoride radical The mechanism is one essentially of calcium deprivation Fibrillary twitchings of the muscles and "paralysis of the central nervous system are produced"¹⁸, these patients presenting the clinical picture of tetany There is also vasomotor paralysis with subsequent fall in blood pressure In acute poisoning where fluoride is taken by mouth there is a strong local irritating action on the mucous membrane of the stomach and small intestine, particularly of the stomach Coagulation of the blood is abolished because of the binding of the calcium with fluoride¹⁸

The sequence of symptomatology is usually as follows Within five minutes after ingestion patients complain of severe epigastric pain followed by severe retching and vomiting, abdominal burning, and general prostration Shortly afterwards diarrhea develops followed by muscular cramps, progressing to spasmodic muscular contractions of the arms and legs When seen by the physician, the patient is usually in mild shock In addition cyanosis of the skin and mucous membranes, excessive perspiration and salivation, with corresponding great thirst, has also been frequently observed, death occurring in most cases from three-quarters of an hour to four hours after the onset, although in some cases it is delayed for twelve hours Death is said

*Read before the Massachusetts Psychiatric Society February 27 1935

†Maletz, Leo—Assistant Physician, Danvers State Hospital For record and address of author see This Week's Issue page 380

to be due to failure of the cardiorespiratory center in the medulla, usually occurring quite suddenly. Rigor mortis is said to set in prematurely. The lethal dose for human beings has been estimated at approximately five grams.

The treatment recommended is gastric lavage with ten per cent aqueous solution of calcium chloride or lime water, copious amounts being used. This procedure converts the soluble sodium fluoride to insoluble calcium fluoride. Magnesium sulphate produces the same effect. Tetany, which is produced by the binding of the fluoride with serum calcium, may be combated by the intravenous administration of ten per cent calcium chloride or the intramuscular injection of parathormone. Shock treatment should be instituted. Despite this treatment patients may expire suddenly, Sharkey and Simpson having reported a case in which death occurred suddenly after the patient had apparently improved.

REPORT OF A FATAL CASE.—This case presented the characteristic features observed by other authors. The patient (H. F.) aged forty-one was a very well developed muscular male individual who had rarely been ill previously. On the morning of September 26, 1934 the patient was working in the kitchen assisting the chef to prepare a batch of hard sauce consisting essentially of powdered sugar and butter. While mixing the sauce the patient sampled quite a liberal quantity. The time interval elapsing from the ingestion of the hard sauce to the onset of symptoms could not be determined but appeared to be within the range of a few minutes to one hour. The patient reported to the chef that he felt sick and that there seemed to be something wrong with the sauce. He left the kitchen and went outdoors where overcome by weakness, he was compelled to lie down. He then developed nausea, retched violently and succeeded in expelling most of the gastric contents. Following this he perspired profusely. The patient, when seen was in mild shock and complained of marked weakness. His skin was cold and clammy, temperature 97.0, pulse rapid 120. Gastric lavage was immediately instituted with four per cent sodium bicarbonate solution. Shock treatment was given. A saline purgative magnesium sulphate two ounces was administered. At this time the nature of the poison was not known. The patient responded to the treatment, the temperature approached normal and the nausea and vomiting subsided. Several hours after the onset the patient commenced to complain of generalized muscular cramps involving particularly the facial muscles. The muscular cramps lasted several hours and then began to subside. At this time it was felt that the patient's general condition was much improved when suddenly while attempting to talk to an attendant he complained of shortness of breath and marked difficulty in breathing became useless and suddenly expired six hours after the onset of symptoms. Blood studies performed shortly prior to death revealed a white blood count of 20,600 differential count: Polys. ninety-two per cent, Lymphocytes six per cent, Monocytes two per cent, Basophils 1/3 per cent. Blood serum calcium performed on postmortem blood was 5.8 mg. per 100 cc.

The autopsy performed by Drs. Anna M. Allen and Charles C. Joyce on the following day revealed the following findings. The face had a distorted appearance, the eyes were sunken, conjunctivae in-

jected pupils unequal, the left 0.4 cm. the right 0.6 cm. There was a continuous oozing of dark red liquid blood from the cut blood vessels of the muscles. Along the right border of the heart and posteriorly were numerous small epichordal hemorrhages. The posterior aspect of both lungs presented many petechial subpleural hemorrhages. The bronchial mucous membrane was slightly congested. On section there were diffuse reddish patches scattered throughout, that appeared to be extravasations of blood. The intestines were a grayish yellow in color thin walled, shrunken very slightly distended and the blood vessels in the walls were engorged. The contents of the small and large intestines were liquid throughout and the mucosa somewhat swollen and creamy white in color. The duodenal mucous membrane showed a few small, irregular reddened patches scattered here and there. Kidneys. Weight 350 grams. The surfaces were smooth and deep pink in color. The organs were firm capsules thin stripped without difficulty revealing a smooth congested cortex. On section the cut surfaces were considerably congested and swelled slightly over the capsule. (Extreme acute passive congestion with advanced cloudy swelling of the kidneys has been reported by other authorities.) The brain in this case was negative except for congested cortical blood vessels. Other organs were not remarkable.

In investigating the source of the fluoride it was determined that the powdered sugar had been contaminated with roach powder and in this way the fluoride had been introduced. Roach powder bears a close resemblance to powdered sugar. Samples of the roach powder, hard sauce, powdered sugar as well as the stomach and contents, cecum and contents, spleen, heart and heart's blood and sections of the liver, brain, kidneys, lungs and large intestine were sent to Dr. Boos, toxicologist, for examination.

Analysis of the powdered sugar revealed thirteen per cent roach powder. The hard sauce as prepared contained eleven per cent roach powder. The roach powder was found to consist of 55.9 per cent sodium fluoride and 44.1 per cent of sodium silicofluoride. Analysis of the organs was as follows. The appearance of the stomach mucosa was eloquent of the terrific local irritant action of the fluoride preparation, contained brown fluid, proved to be altered blood. The stomach yielded a trace of fluoride. The cecum contained a brown fluid of thin pea soup consistency. This fluid had a pronounced alkaline reaction and gave a test for magnesium fluoride and sulphate. It appeared that the amount of magnesium present in the cecal contents was not sufficient completely to convert the alkaline sodium fluoride into neutral magnesium fluoride. The cecal contents by analysis contained approximately six grains of this powder. The liver, kidneys, spleen, large bowel, lungs, heart, and heart's blood all yielded a positive test for fluoride varying however considerably in degree. The sequence of these organs as given indicates the order of intensity of the test.

The chef had also partaken of the sauce however taking only a very small quantity. He noticed that the hard sauce tasted peculiar and ordered the entire batch thrown out. Within a few moments he also experienced the same symptoms of weakness, nausea and vomiting but to a lesser degree. When seen by a physician shortly after the nausea and vomiting had subsided and the patient at this time complained only of weakness and had no other complaints. He very rapidly recovered his strength and in several hours felt quite well. The only treatment was two ounces magnesium sulphate administered orally.

SUMMARY

We are reporting an additional fatal case of sodium fluoride poisoning with a general review of the subject

The symptomatology is as follows The patient after ingestion of the poison soon complains of severe epigastric pain, followed immediately by nausea, severe retching and vomiting, and generalized prostration These symptoms are shortly after followed by diarrhea and muscular cramps, progressing to spasmodic contractions of the extremities, and clinical evidence of tetany

The treatment recommended is as follows copious gastric lavage with ten per cent calcium chloride, weak lime water, or magnesium sulphate This procedure converts the soluble fluoride into insoluble calcium or magnesium fluoride The tetany should be combated by intravenous calcium fluoride or intramuscular parathormone Shock treatment should be instituted

Pathological examination reveals local irritating action on the mucous membrane of the stomach and intestine, as exemplified by minute hemorrhages and congestion Irritation of the lungs also occurs as evidenced by congestion of the bronchial mucous membrane and petechial subpleural hemorrhages Extreme, acute passive congestion with advanced cloudy swelling of the kidneys has also been reported¹⁶ Coagulation of the blood is abolished because of the binding of the calcium with fluoride

Sodium fluoride and sodium silicofluoride are common ingredients of insecticides and roach powders and may be easily mistaken for Epsom salts, powdered sugar, or baking powder The author wishes to emphasize again the toxicity

of these substances and to suggest as others have, that containers be properly labeled "Poison." Disguising these powders by coloring matter would appear wise

The author wishes to acknowledge the assistance and cooperation of Dr Clarence A Bonner and Dr Melvin Goodman

PAN AMERICAN GROUP ELECTS DR ROMERO AS SECRETARY

Dr Herman Romero of Chile was elected secretary of the Pan American Medical Association, at the recent "Floating Congress" of the association

Dr Romero was also elected one of the regional administrators for Chile, the announcement added, and the Academy of Medicine of the University of Sao Paulo, Brazil, has made him an honorary member

Dr Arturo Scroggie Vergara of Chile was named one of the vice presidents of the association, which is composed of leading physicians and surgeons from North, South and Central America.

Physicians after attending the Rio de Janeiro meeting of the association express themselves as deeply appreciative of the courtesies extended to them by the Brazilian Government They further report that the congress proved highly instructive—*N Y Times*

MORTALITY RATES

Telegraphic returns from 86 cities, with a total population of thirty-seven millions for the week ending August 10, indicate a mortality rate of 9.5 as

against a rate of 9.7 for the corresponding week of last year The highest rate (21.7) appears for Nashville, Tenn, and the lowest (4.3) for Yonkers, N Y The highest infant mortality rate (24.6) appears for South Bend, Ind., and the lowest for Camden, N J, New Bedford, Mass, Omaha, Nebr, Peoria, Ill, Somerville, Mass, Spokane, Wash., Tacoma, Wash., Trenton, N J, Waterbury, Conn, and Youngstown, Ohio, which report no infant mortality

The annual rate for 86 cities is 11.8 for the thirty-two weeks of 1935, and the same rate appears for the corresponding period of the previous year

SUMMARY OF DEATHS AND DEATH RATES (ANNUAL BASIS) FROM AUTOMOBILE ACCIDENTS PER 100,000 ESTIMATED POPULATION FOR 86 CITIES FOR CORRESPONDING PERIODS OF 1935 AND 1934

	Week ending		First 32 weeks	
	Aug 10, 1935	Aug 11, 1934	1935	1934
Total deaths	148	151	5,030	5,063
Death rate	20.6	21.0	21.9	22.0
Deaths due to accidents in city	109	112	3,987	4,034
Death rate	15.2	15.6	17.4	17.6

CASE 21341

PRESENTATION OF CASE

A thirteen year old American schoolboy entered complaining of the spitting of bright red blood

At the age of three his mother noted blood in his stools associated with weakness and pallor. At that time he was studied at another hospital for about a month following which his spleen was removed. The patient improved rapidly and was discharged in two weeks. He had no recurrences of the melena and appeared to be in good physical condition.

On the evening before admission he complained of a sore throat and went to bed quite early. The following morning his throat was still sore and in addition he complained of mild frontal headache. In the early afternoon he developed nausea which was soon followed by the vomiting of a cupful of rather thick black material not recognized as food. About fifteen minutes later he again vomited about a pint of bright red blood with clots. Six hours before entry he passed a loose, watery, almost black stool and a few hours later frank red blood. A few hours before entry he vomited again. This time there were many clots and bright red blood amounting to about a quart.

During the past ten years he had been quite pale although active and apparently entirely healthy. There had been no previous attacks of bleeding, hematuria, or red or tarry stools. He did not bruise easily.

His father and mother were both living and well. One brother, aged sixteen was living and well. There was no family history of tuberculosis or hemorrhagic manifestations. He had had measles and chickenpox. A tonsillectomy had been performed six years before entry.

Physical examination showed a well developed and nourished boy in no acute distress. The skin was pale. No purpuric lesions were noted. The heart and lungs were negative. The blood pressure was 85/40. There was a left upper rectus scar apparently the site of the previous splenectomy.

The temperature was 102°, the pulse 120. The respirations were 24.

Examination of the urine was negative. The blood showed a red cell count of 2,630,000 with

a hemoglobin of 60 per cent. A smear showed numerous platelets. The white cell count was 14,650, 82 per cent polymorphonuclears. The stools were semisolid and all gave positive guaiac tests. The bleeding time was two minutes, the clotting time one and a half minutes. A Hinton test was negative. A liver function test was normal. The icteric index was 3.

X ray examination showed a slightly dilated esophagus with numerous large venous channels projecting in the mucosa involving the lower two thirds. There was no evidence of obstruction. The stomach and duodenum were normal.

On the day of admission he vomited about 18 ounces of blood half of which was clotted. He was given a transfusion of 500 cubic centimeters. He did fairly well for about a month although he continued to have a slightly elevated temperature. About one month after admission at about 4 a.m. he suddenly vomited a large amount of blood. This was repeated the following day after which he was given a transfusion of 700 cubic centimeters. His red blood cell count dropped to 1,100,000, with a hemoglobin of 35 per cent. He vomited more blood the following day and was again transfused. He developed slight swelling and tenderness of both parotid glands. For the next two weeks there was no further bleeding although his temperature still remained elevated. During the seventh week he began to complain of generalized steady epigastric pain which was not relieved by morphia. His pulse and blood pressure were normal. There was slight spasm in the left upper quadrant although the remainder of the abdomen was very soft. Little peristalsis was heard except in the left upper quadrant lateral to the splenectomy scar, where active, rather high pitched peristalsis was heard. None was seen. At 9 p.m. that day his abdomen was still spastic and peristalsis was now present in the right half of the abdomen and absent in the left. His temperature was 102.2°, the pulse 120. His condition remained about the same and two days later his abdomen had become much more distended. He went into shock and died that day.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON. We have very little data in regard to the first illness. I am going to consider that he had at the age of three the same disease at least to some extent, that he died of and discuss it from that point of view. He had bleeding at the age of three which was apparently related to splenectomy. There are not many conditions you can think of that will show that. I think we can cross out the rarer erythroblastic anemias. I do not feel sure that splenectomy is of value in these cases. This boy is a native born American and certainly has not the Mediterranean type of erythroblastic anemia. If he had the same disease then as now I think we can disregard purpura

because at the present time he has normal bleeding time, numerous platelets and no evidence of purpura in the interval. I will rule out purpura on that basis. Hemolytic jaundice can be considered. He has no evidence of icterus at the present moment and I doubt if he had it then. Therefore, we wonder why his splenectomy resulted in so prompt relief of the bleeding. I think the reason is that the splenic artery was tied off. Cirrhosis of the liver can occur at the age of three and must be considered in this situation, and, finally, the form of splenomegaly which may be associated with cirrhosis of the liver and which also may be associated with obstruction in the splenic and other veins.

We now consider the present illness with the ten year interval of freedom. What bearing has that on the original diagnosis? If he had cirrhosis of the liver with some enlargement of the spleen it seems likely that other symptoms would have become apparent in the interim. He has developed only one new finding, that is, this question of dilated esophageal veins.

X-RAY INTERPRETATION

DR RICHARD SCHATZKI. These pictures represent the lower third of the esophagus. Here is the diaphragm. The esophagus was slightly dilated without evidence of obstruction near the region of the cardia. The normal relief of the esophagus shows narrow, longitudinal, parallel running lines. You do not see them here. Instead, we have these thick bands of decreased density which are characteristic of dilated veins protruding into the lumen.

DIFFERENTIAL DIAGNOSIS CONTINUED

DR RICHARDSON. I take it then that there are esophageal varices in this boy and presumably he is bleeding either from those or from dilated veins in the stomach.

A thirteen year old boy is not usually an alcoholic and the ordinary association of alcohol with portal cirrhosis is perhaps excluded here. If this is cirrhosis it must be considered most likely syphilitic and although we cannot rule that out absolutely there is no evidence of the stigmata of congenital syphilis, and he has a negative Wassermann. That is as far as we can go in ruling it out.

We rule out hemolytic jaundice. He had an icteric index of three and apparently no evidence of recurrent jaundice.

The other problem then is whether this picture can be explained on another basis, namely primary splenomegaly. We do not know that the spleen was enlarged at the age of three. Presumably it was, with some obstruction of the splenic vein and with the possibility that that obstruction had advanced to involve the portal vein and cause portal obstruction with some cirrhosis in association, and also cause dilatation of the esophageal veins.

If we go on to the last part of the story we suddenly discover that he was not, as might have been expected, bleeding to death. We find all the emphasis on the abdomen. I think that is significant. Just what this tinkling peristalsis going from one side to the other is, I do not know, except that he had something causing pain and distention and probably obstruction, enough to cause a good deal of emphasis to be put on it in a long paragraph in this history.

If we assume he has an obstructive lesion in the portal vein, it is proper to guess that it might involve some of the mesenteric radicles. One other thing about the various rare blood diseases—there is no evidence that such existed. We have no description of the smear. We assume it is relatively normal. There is no evidence of a gastrointestinal ulcerative lesion so it comes down to a question of cirrhosis of the liver or splenomegaly, probably of the type with obstruction in the splenic, portal, and possibly of the mesenteric veins. I have avoided the term Banti's disease because I do not know just what it means. As it was described originally it is a condition with an enlarged spleen and gastrointestinal hemorrhages with thromboses of the splenic vein. I will in this case make a diagnosis of splenomegaly with obstruction in the veins that I have mentioned, probably with secondary changes in the liver of a mild cirrhotic nature.

CLINICAL DISCUSSION

DR RICHARD M SMITH. I saw him at the first admission to the Children's Hospital. At that time he did have an enlarged spleen. He came in with an attack of hemorrhage very much like the one for which he entered here. We considered at that time that the diagnosis was the condition which Dr Richardson has refused to name and about which we felt very much the same as he does. It is the condition described under the title of Banti's disease or splenic anemia, or thrombophlebitis of the splenic vein. We believe that the primary lesion is due to obstruction and not to dysfunction of the spleen as was originally believed. The picture is easily explained on that basis. A collateral circulation is established with marked esophageal varices from which bleeding takes place.

We have seen quite a series of children with this condition at the Children's Hospital, fifteen altogether. They have all died of uncontrollable hemorrhage. There is a child at the hospital now whom I saw this morning who has been bleeding for three days and may possibly die. The removal of the spleen seems to offer temporary relief. The patient presented here has gone the longest of any of our series without a recurrence of bleeding. We have another child who went eight years. Eventually they all have a hemorrhage and die due to the inability to

control the bleeding. There are two or three other matters which ought to be mentioned in connection with this condition. Dr Richardson spoke of the abdominal pain which is not an unusual characteristic when you have an advancing thrombosis involving other radicles of the portal system. It would be interesting to know what the platelet count was after the hemorrhage was over. I notice in the report that the platelets were elevated. It has been noted and it has been our experience that with continued elevation of the platelet count there is likely to develop a secondary thrombosis. We know it is a common or not a rare complication following splenectomy for any reason and in this condition it is more likely to occur than in others. It is also true that some of these children develop an intestinal obstruction due apparently to adhesions. We have had one such patient and there are others reported in the literature. This attack of bleeding followed an acute infection. It has been true in a considerable number of our cases that some intercurrent infection apparently precipitates a recurrence of the bleeding. We have been interested in trying to consider the possibility of what we should do next in order to control the bleeding. Removing the spleen of course takes out of the portal circulation roughly twenty per cent of the blood and yet it is not sufficient to prevent recurrence of hemorrhage although they may be well for a considerable period of time. It has been suggested that tying the coronary vessels or vessels in the gastrophatic omentum may be of value. It has been tried in a number of cases apparently with some success. We were greatly disappointed in the child who is now in the hospital bleeding, because her coronary vessels were tied about four months ago and we hoped that it would be effective in preventing subsequent hemorrhage. It has not been. Another suggestion is that one might attempt to establish better collateral circulation through the omentum and abdominal wall. I think that offers some hope, although it has not been particularly successful in varices due to cirrhosis of the liver. The patient of ours who has gone the longest, with the exception of this boy, without a recurrence of hemorrhage after splenectomy did subsequently have a hemorrhage. Dr Ladd operated upon her and tied the coronary vessels. In that child the collateral circulation was well established. The omentum was bound firmly to the abdominal wall. I do not know whether it is significant that the child who has had hemorrhage eight or ten times presented at operation no appearance of gluing of the omentum to the abdominal wall and the superficial vessels on the abdomen were not enlarged. Another child whom we have followed for eight years has never had a recurrence of hemorrhage but has had repeated attacks of abdominal pain which we have interpreted as fresh thromboses. She has a remarkable en-

largement of the vessels of the chest and abdomen. In other words, she has established a circulation through the omentum. At the present time we can promise very little to benefit this condition and can predict almost certainly recurrences of hemorrhage and probably a fatal outcome.

DR. BETH VINCENT. I came in touch with this case in the medical wards and saw the patient frequently during the time he was under observation in the hospital. We recognized the condition and hoped we might be able to do something such as Dr Smith has suggested but never had the opportunity because the acute abdominal episode intervened before the boy was in sufficiently good condition, following the hemorrhages, to warrant operation. At the time of the acute episode the diagnosis was either intestinal obstruction due to adhesions following splenectomy or a thrombophlebitis of the portal vein and radicles resulting in gangrene and perforation of the intestine, an evident diagnosis, I think, to make under the circumstances.

In considering this case it is well to review what Dr Osler called splenic anemia. You will remember his definition was "a chronic progressive disease due to intoxication of unknown origin, associated with splenomegaly, anemia, leukopenia, and with a pronounced tendency to massive hemorrhages from the stomach." He said nothing, I think, in his description about any lesion of the portal vein or the splenic vein. I shall leave it to Dr Mallory to comment on that phase of the subject.

I want to devote just a moment to the treatment that Dr Smith has suggested. We are pretty certain what the result is going to be in these cases of portal thrombophlebitis. Splenectomy, usually, does not prevent bleeding from the esophageal varices and the patients die of hemorrhage or else they die of a recurrence or an extension of the portal thrombophlebitis, which results, as in this case, in mesenteric thromboses and gangrene of the intestine. To take out the spleen in these cases is rational, I think, because by removing the spleen and tying the splenic arteries you do for a time, certainly, diminish greatly the amount of blood that must return through the portal system. When the return of blood through the portal system is obstructed it passes upward by a collateral circulation which gives rise to esophageal varices. These are susceptible to trauma, they rupture, and the patient has massive hemorrhage. If one has taken out the spleen and wishes to go farther, to tie off the coronary vessels that are conducting the blood into these varices is rational enough if you can supply some other avenue for the blood to go back into the heart. The only way I can conceive of doing that is by an omentopexy, or possibly by attaching a portion of the omentum to the under surface of the liver to conduct some of the blood back through the

liver There is only one other method that I can suggest, if one has the courage to do it That is to make an Eck fistula, an anastomosis between the mesenteric vein and the vena cava I do not know just what the end result would be of shunting most of the portal blood through the vena cava with very little going through the liver These cases often live a long time, in spite of the hemorrhages There was a girl of twenty-one in the ward recently When she was seven years old, under the same circumstances as this case, I took out the spleen She had hemorrhages before the splenectomy and has had them ever since Perhaps sometime we may attempt one of the operations I have suggested

CLINICAL DIAGNOSES

Banti's disease (postsplenectomy) with esophageal varices and hemorrhage
Retrograde mesenteric venous thrombosis
Peritonitis

DR WYMAN RICHARDSON'S DIAGNOSES

Splenomegaly
Thrombosis of splenic, portal and mesenteric veins
Slight cirrhosis of liver?

ANATOMIC DIAGNOSES

(Banti's disease)
Thrombosis, old, of portal and splenic veins
Thrombosis, fresh, of superior and inferior mesenteric veins
Gangrene of the ileum, with perforation
Peritonitis, acute generalized.
Esophageal and gastric varices
Operative scar Splenectomy

PATHOLOGIC DISCUSSION

DR TRACY B MALLORY The autopsy in this case was done with extreme care by Dr Castleman, and I think gives a very complete answer to most of the clinical picture We started with a firm conviction that we were going to find obstruction in the portal circulation Of course, the commonest cause of that is cirrhosis of the liver and about two-thirds or three-fourths of the cases showing a clinical picture like this will show cirrhosis of the liver There are, however, a very significant number of cases in which the liver is perfectly normal, and the first glance at the liver showed that that was probably the case here Our attention was therefore immediately turned to the portal vein and it was found that that was completely thrombosed, and most of its radicles as well It was quite evident that these thrombi were of distinctly varying age In gross we could find an old, fibrous, completely organized thrombus, involving almost completely the portal and the remnants of the splenic vein When we looked for the superior

mesenteric vein we found two vessels of almost equal size running parallel courses One of them was completely obliterated by an old organized thrombus, whereas the parallel vessel running right along beside it, evidently a collateral which had formed some years ago, completely filled with fresh thrombus The terminal seven feet of ileum were gangrenous, and there was beginning peritonitis

When we came to examine the vessels microscopically we were able to carry back the story a little farther There were three distinguishable ages of thrombi First there was an old organized and a partially recanalized one, years old, which without doubt went back to the onset of his present illness, more than ten years ago Secondly, there was a much more recent thrombus which nevertheless showed some degree of organization and might be anywhere from two to five weeks old The development of that thrombus probably coincided with the onset of the acute hemorrhages Then there was a final fresh thrombus which accounted for the gangrene of the intestine and exodus

The liver was essentially normal It was not cirrhotic There were in it four small localized nodules, each about one centimeter in diameter, which were perfectly round and caseous On microscopic examination they showed a caseous center with a fibrous capsule, but no giant cells or mononuclear phagocytes, nothing to identify their origin They could be healed solitary tubercles They could be gummata, although there is no evidence of syphilis in this case I think it is conceivable that they could be partially healed infarcts of the liver The remainder of the liver was normal Functionally they could not have been of any significance

We have had several cases fitting more or less closely the so-called Banti's syndrome in the last four or five years that have interested us a great deal because there has been little or no cirrhosis but we have been able to demonstrate thrombosis of the splenic or the portal vein In 1910 Dr Wharthin reported seven cases showing the characteristics of the splenic anemia symptom complex and in all of these he was able to show obstruction of the portal system We have had only one case out of a half dozen here in which we have failed to show the same thing That obstruction of the splenic vein can easily be missed was shown very prettily by one case which we have already presented here Some of you will remember it, a man with a splenomegaly of years' duration, no anemia, until he suddenly had an extremely severe hemorrhage He was given a great many transfusions, put back into shape for a splenectomy, which was done with apparent success, although some weeks after he left the hospital he died suddenly, probably of pulmonary embolus At the time of operation it was impossible to identify the splenic vein The

same was true on gross examination of the specimen but when the hilus of the spleen was sectioned we were able with the aid of the microscope to demonstrate the remnants of the splenic vein with its characteristic elastic lamina still present and its lumen completely filled with fibrous tissue and small canalizing vessels. The surrounding tissue was full of very thin walled widely dilated newly formed veins. That is a case which would have gone down in the record as one of splenic anemia without evidence of portal obstruction if it had not been examined microscopically with this particular point in view. I feel very strongly that there are few if any cases of the splenic anemia syndrome in which you cannot find portal obstruction. It may be necessary to use special technique and a great deal of care to demonstrate it, however.

CASE 21342

PRESENTATION OF CASE

A sixty five year old English steamfitter entered complaining of abdominal pain of two weeks' duration.

Approximately one and a half months before entry he began to have attacks of diarrhea followed by constipation about once a week. One month before entry he had tarry stools on one or two occasions. Two weeks later he awoke with a dull aching pain in the abdomen about the region of the umbilicus. He was constipated at the time and vomited. The pain gradually grew worse for a few days and then was relieved by a bowel movement. During this period he had similar attacks two or three times a week, each associated with severe constipation and preceded by diarrhea. Two days before entry the pain suddenly became very severe and was accompanied by severe vomiting day and night. The vomitus consisted of recently eaten food and a white frothy phlegm. A physician prescribed an enema which relieved the pain. He had one red stool during this period. His appetite had been good. There was no jaundice. He had lost a great deal of weight but did not know how much.

The family and marital histories are non contributory.

The past history is negative except for a slight to moderate urinary difficulty consisting of burning, dribbling, incontinence and nocturia. He passed only a small amount of urine each time. He denied venereal disease.

Physical examination showed a well-developed but poorly nourished man. The skin was dry. The heart and lungs were negative. The blood pressure was 140/85. In the right lower quadrant there was a firm, non tender, round mass about 5 centimeters in diameter. The prostate was normal.

The temperature was 99°, the pulse 88. The respirations were 18.

The urine was negative. The blood showed a red cell count of 3,840,000 with a hemoglobin of 60 per cent. The white cell count was 9,500.

A barium enema passed as far as the ileocecal valve but could not be forced through the valve into the ileum. There was distinct defect in the cecal tip. The remainder of the bowel appeared normal.

A phenolsulphonphthalein test showed 45 per cent excretion after three hours, 15 per cent being excreted in the first hour. The non protein nitrogen of the blood was 36 milligrams per cent.

On the third day operation was performed. On the first postoperative day he developed coarse tracheal rales. Numerous rhonchi were heard throughout both lungs, especially at the bases. He rapidly failed and died on the third postoperative day.

DIFFERENTIAL DIAGNOSIS

DR. MARSHALL K. BARTLETT. A history of weekly attacks of alternating diarrhea and constipation for six weeks, with tarry stools on two occasions, in a man of sixty five years of age, should mean malignancy of the colon until such a lesion is definitely ruled out.

The attacks became worse and more frequent. For the two weeks before admission they occurred two or three times a week. They were accompanied by pain referred to the region of the umbilicus and associated with severe constipation and vomiting. On each occasion the pain was finally relieved by a bowel movement. The exact nature of the pain is not described. There was one "red stool", probably due to fresh blood.

This is the story of repeated episodes of subacute intestinal obstruction, with spontaneous relief of each attack. The nature of the vomitus is not of particular significance. There had been extensive weight loss.

The urinary symptoms revealed in the past history do not seem to fit into the picture and I do not believe that they are related to the patient's present disease.

Physical examination confirms the loss of weight, and there is a firm non tender round mass about 5 centimeters in diameter felt in the right lower quadrant. Barium enema shows a distinct defect in the cecal tip, and no barium passed into the ileum. Blood examination shows a moderate anemia. The nonprotein nitrogen is normal and the phenolsulphonphthalein test shows an excretion of the dye which is within the lower limits of the normal range.

The other conditions which must be considered in the differential diagnosis of this lesion in addition to malignancy, are appendiceal abscess and tuberculosis of the cecum.

In a man of sixty five, tuberculosis of the

cecum would be quite a rare lesion. Gross hemorrhage from an acid-fast lesion in this region, while possible, is much less common than from a malignant tumor. It is also unlikely that a tuberculous process of sufficient extent to give the hemorrhage and weight loss that this man has had would remain localized as a "firm non-tender mass 5 centimeters in diameter."

Appendicitis is, of course, the most common lesion in the right lower quadrant and must be considered in every case involving this region regardless of the age of the patient. Hemorrhage from an appendix abscess is exceedingly rare, but it does occur. I know of one such case. Here again the discrete localized nature of the palpable mass is not suggestive of an inflammatory process originating in the appendix.

Although both tuberculosis and appendicitis must be considered, it seems to me that all the data in this case point to a malignant growth of the colon, presumably carcinoma, with intermittent attacks of intestinal obstruction, except the location of the lesion. Carcinoma of the cecum typically ulcerates and bleeds but does not cause obstruction. In this case, however, with the lesion in the tip of the cecum, it would seem possible that the growth has involved the region of the ileocecal valve sufficiently to cause the degree of intestinal obstruction which this patient has had. The fact that none of the barium enema passed into the ileum does not help particularly one way or the other, as this may happen with a normal ileocecal valve.

The most probable diagnosis seems to be a malignant lesion of the cecum, probably carcinoma, with repeated attacks of subacute intestinal obstruction. On the day after operation he developed a major pulmonary complication, the exact nature of which it is difficult to make out from the facts given. He died on the third postoperative day. My impression would be that he had a bilateral bronchopneumonia.

CLINICAL DIAGNOSES

Carcinoma of the cecum
Bronchopneumonia

DR MARSHALL K BARTLETT'S DIAGNOSES

Bilateral bronchopneumonia

ANATOMIO DIAGNOSES

(Adenocarcinoma of the ileocecal valve) with a metastasis to the liver
Operative wound. Resection of the cecum and portions of the terminal ileum and transverse colon and ileotransverse colostomy

Lobar pneumonia, right lower
Bronchopneumonia, left lower
Peritonitis, acute generalized
Pleuritis, chronic fibrous
Endocarditis, acute terminal, aortic

PATHOLOGIC DISCUSSION

DR. TRACY B MALLORY. The patient was operated upon under ether anesthesia and a growth about the size of a tennis ball was found in the terminal portion of the cecum close to the ileocecal valve. A one stage operation which included resection of the cecum, ascending colon and 15 centimeters of the ileum was done. The cut end of the ileum was anastomosed to the transverse colon.

Examination of the specimen in the laboratory showed that, as Dr Bartlett had predicted, the obstruction had been produced by involvement of the ileocecal valve. The tumor completely encircled it and also involved the blind end of the cecum at the base of the appendix. It showed several areas of ulceration, the largest 1.5 centimeters in diameter, and to one of them may safely be attributed the single bowel hemorrhage. Although several lymph nodes were found which seemed definitely enlarged, microscopic examination failed to show any evidence of metastasis to them.

The autopsy showed a slight degree of generalized peritonitis although the anastomosis between the ileum and the transverse colon appeared in perfect condition and there was no evidence of infection about the sutures. Death was caused without much question primarily by pulmonary involvement. There was a massive lobar pneumonia of the right lower lobe and several small patches of more recent bronchopneumonia in the left lower lobe. Both apices showed extensive old tuberculous scars with numerous small areas of calcification. If a chest plate had been done the differential diagnosis would probably have been made more difficult. The heart was normal in size but showed marked calcification and evidence of a recanalized thrombus in the circumflex branch of the left coronary artery. There were no areas of infarction, however. A slight acute terminal endocarditis was present in the aortic valve. The liver showed a single small metastatic nodule, one centimeter in diameter, so far up beneath the diaphragm on the right lobe that it is not surprising that the surgeon had not felt it. The gall bladder contained a small stone. The kidneys were within normal limits in view of the patient's age. The urinary symptoms were readily explained by a distinct prostatic hyperplasia which was sufficiently marked in the median lobe to have resulted in hypertrophy and moderate trabeculation of the bladder wall.

THE MEDICAL SOCIETY AND THE MEDICAL PROFESSION

IN the Annual Discourse delivered at the June meeting of the Massachusetts Medical Society in Boston, Brace Paddock had written: "In order for the state society best to fulfill its purpose it must embrace the whole profession." Death had closed his lips only two weeks before the Annual Meeting so that he could not defend his thesis, but it stands as a challenge to the Society.

The challenge lies in the conflict of realities of 7014 licensed physicians in this state, only 5054 are members of the Massachusetts Society and many of these 1960 physicians are not wanted in the Society. The problem presented by the physicians who do not want to join the Society need not be considered now.

Why is it that so many physicians are not wanted in the Society? It is this situation that presents the challenge. Without resorting to circumlocutions, the substantial reason is that the Society, jealous for the traditions of the

past, and the high standards of medical practice which it has consistently attempted to preserve and uphold and raise, and still attempts to maintain, fears the influence of these "ineligible" physicians. The justification for this fear need not be gone into now, but its confirmation is widespread throughout the United States among persons and organizations interested in the welfare of the medical profession and in the protection of the public against unqualified medical practitioners. Many of these physicians, ineligible for membership in the Society in Massachusetts, would be ineligible even to take the examination for licensure in any other state.

But these "ineligibles" are practitioners of medicine duly licensed by the Massachusetts State Board of Registration in Medicine! There is then a sharp difference of opinion as to reasonable requirements for the practice of medicine between the Board acting under the statute and the Society.

Perhaps the Board ought to give a more rigorously exclusive examination there is no numerical dearth of physicians in Massachusetts and if the number of new practitioners were markedly reduced over a period of years, the public might suffer little harm.

It has been suggested that the statute should be changed, and if generally accepted standards are taken as a criterion, this should be done. There seems to be no reason why Massachusetts should favor commercialism, by permitting the continuation of the giving of low grade medical education in schools which it has chartered. The good name of the Commonwealth suffers.

Perhaps the Society should lower its standards and adjust them to the facts of medical practice as they exist in Massachusetts. In any case the present situation is intolerable and on the Society as the self appointed guardian of the profession lies the chief responsibility for bringing about the much needed change, whatever wisdom may show it to be.

SERODIAGNOSTIC TESTS FOR SYPHILIS

THE recent report* of the committee investigating serologic methods for the diagnosis of syphilis emphasizes the value of the techniques devised during the past fifteen years. There are two general methods in vogue, the modifications of the old Wassermann complement fixation technique and the variations of the precipitation method. The latter are simpler in principle since they require the use of but one reagent (antigen) in addition to the patient's serum.

Cumplings, H. B.; Hazen, H. H.; Sanford, A. H.; Kneier, J. W.; Simpson, W. M. and Vonderlehr, R. A. J. A. M. A., 1914 2015 1915

herniation or rupture of the intervertebral disc is more descriptive than "prolapse of the nucleus pulposus" as coined by Schmorl (Fig 1)

HERNIATION OF DISC INTO LUMBOSACRAL CANAL

Incidence Of the twenty-three patients with this type of lesion, only four were women. At the time of operation the youngest was twenty years, the oldest sixty-four. The ages thirty to

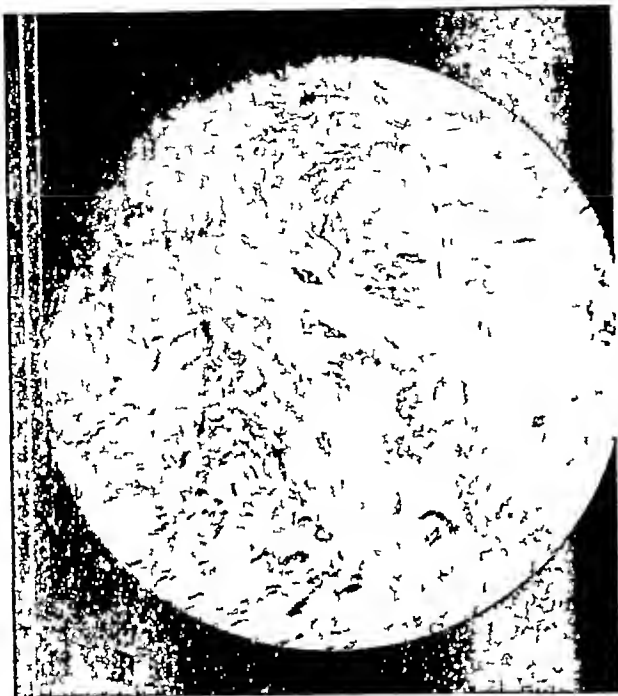

FIG 1 Microphotograph from specimen obtained at operation L C M G H No 325587. Material from annulus on the left and from nucleus on the right.

fifty furnished two-thirds of all the cases. No racial disposition was indicated.

Etiology A satisfactory history of antecedent trauma was obtained from fourteen patients and specifically denied by five. In only seven (one-third of all the cases) did it seem certain that an accident was followed immediately by the symptoms for which later the operation was performed.

It would be of interest to correlate as factors in causing rupture of a disc the physical development, body mechanics and nutritional state of the patients. This study, however, was not made. All we can say is that the work engaged in at the time of the rupture represented a wide variety of indoor and outdoor activity and that the individuals afflicted were not conspicuous for under- or over-development, nor were they otherwise, with one exception, chronic invalids.

As a typical example of the group under discussion the following case history is given.

CASE 1 D S., No 342673 M G H, a man of slight build, forty-four years old, machinist in a cotton mill, complains of low back pain of two years' duration, radiating to the right but-

tock and down the posterior aspect of the right thigh and leg. There is no pain elsewhere and no difficulty with sphincters. The present symptoms are similar to pain experienced six years ago which came on suddenly when lifting a heavy bale of cloth, necessitating bed rest for five weeks. In the intervening four years he has been well and active.

He stands and walks with a list forward and to the right, bends body forward with caution and associated flexion of the right knee. There is tenderness on pressure over the right sacroiliac joint and increased pain in this region on straight leg raising which is greatly limited on this side. Although gluteus, hamstrings and calf appear a little softer and smaller on the right, than on the left side, no appreciable weakness is observed, and sensory loss is limited to hypesthesia of skin over the external aspect of the lower right leg. The sole reflex abnormality is absence of the right Achilles jerk.

Combined lumbar puncture with needles at L1-2 and L5-S1 spaces shows no block, both fluids clear, colorless and in every respect normal except for elevation of protein, 59 mg and 67 mg respectively. (It is almost certain that both needles were above the tumor.)

X-ray after lipiodol injection into L1-2 space shows a concave defect in the lipiodol column outlining a rounded mass in the canal on the right side between the fifth lumbar vertebra and the sacrum.

At operation a piece of ruptured disc was found at the place indicated by lipiodol, and observed to press directly on the fifth lumbar root.

Symptoms and Signs As the site of the lesion in our cases varied so little, and the size of the herniated portion of the disc was found to be so uniform, it is not surprising that symptoms and signs should be similar. It is more in the course of the disease than in the nature of symptoms that we find individual differences.

Sensory Symptoms and Signs Pain was the first symptom in every case, and it was for relief of pain that all except two sought relief, in two only, disability was of prime importance. The pain was usually described as an ache in the low back, usually just to one side or the other, becoming paroxysmal on turning, stooping, coughing and sneezing whereupon it would radiate outward over the buttock and down the back of the thigh, and at times the back of the leg also. Not infrequently the pain commenced in the mid-line and radiated down the back of both thighs, but unilateral distribution was the rule, even though symptoms had lasted many months. Pain in the perineum also was present in three patients. In only one was the pain referred to the anterior aspect of the thigh.

To minimize the pain, many patients assumed a slight stoop in walking and standing, and on examination the lumbar muscles were found in protective spasm. Tenderness even on gentle percussion over the low spine, lumbosacral ligaments and sacroiliac joint was commonly present, and yet rarely was the sciatic nerve tender on deep palpation. Notwithstanding, straight

SUBSCRIPTION TERMS: \$4.00 per year in advance postage paid for the United States Canada \$7.00 per year \$8.00 per year for all foreign countries belonging to the Postal Union.

Material for early publication should be received not later than noon on Saturday. Orders for reprints must be sent to the Journal office 8 Fenway.

The Journal does not hold itself responsible for statements made by any contributor.

Communications should be addressed to The New England Journal of Medicine 8 Fenway Boston Mass.

THE MEDICAL SOCIETY AND THE MEDICAL PROFESSION

In the Annual Discourse delivered at the June meeting of the Massachusetts Medical Society in Boston, Brace Paddock had written "In order for the state society best to fulfill its purpose it must embrace the whole profession." Death had closed his lips only two weeks before the Annual Meeting, so that he could not defend his thesis, but it stands as a challenge to the Society.

The challenge lies in the conflict of realities of 7014 licensed physicians in the state, only 5054 are members of the Massachusetts Society and many of these 1960 physicians are not wanted in the Society. The problem presented by the physicians who do not want to join the Society need not be considered now.

Why is it that so many physicians are not wanted in the Society? It is this situation that presents the challenge. Without resorting to circumlocutions, the substantial reason is that the Society, jealous for the traditions of the

past, and the high standards of medical practice which it has consistently attempted to preserve and uphold and raise, and still attempts to maintain, fears the influence of these "ineligible" physicians. The justification for this fear need not be gone into now, but its confirmation is widespread throughout the United States among persons and organizations interested in the welfare of the medical profession and in the protection of the public against unqualified medical practitioners. Many of these physicians, ineligible for membership in the Society in Massachusetts, would be ineligible even to take the examination for licensure in any other state.

But these "ineligibles" are practitioners of medicine duly licensed by the Massachusetts State Board of Registration in Medicine! There is then a sharp difference of opinion, as to reasonable requirements for the practice of medicine between the Board acting under the statute and the Society.

Perhaps the Board ought to give a more rigorously exclusive examination there is no numerical dearth of physicians in Massachusetts, and if the number of new practitioners were markedly reduced over a period of years, the public might suffer little harm.

It has been suggested that the statute should be changed and if generally accepted standards are taken as a criterion this should be done. There seems to be no reason why Massachusetts should favor commercialism, by permitting the continuation of the giving of low grade medical education in schools which it has chartered. The good name of the Commonwealth suffers.

Perhaps the Society should lower its standards and adjust them to the facts of medical practice as they exist in Massachusetts. In any case the present situation is intolerable and on the Society, as the self appointed guardian of the profession lies the chief responsibility for bringing about the much needed change whatever wisdom may show it to be.

SERODIAGNOSTIC TESTS FOR SYPHILIS

THE recent report* of the committee investigating serologic methods for the diagnosis of syphilis emphasizes the value of the techniques devised during the past fifteen years. There are two general methods in vogue the modifications of the old Wassermann complement fixation technique and the variations of the precipitation method. The latter are simpler in principle since they require the use of but one reagent (antigen) in addition to the patient's serum.

Cummings H. H., Hazen H. H., Sanford A. H., Senechal W. W., Simpson, W. M., and Vonderlich R. A. J. A. M. A., 1934; 10:125-1255

Identical samples of blood taken from known syphilitics and non-syphilitics were submitted in the present study to the authors of various American methods of testing. Every precaution was taken to insure conditions approximating those met with in practice.

For the detection of syphilis when present, several of the precipitation methods appear distinctly superior to all but one of the complement-fixation tests. The number of specimens tested was perhaps not large enough to allow accurate evaluation of the liability of the tests to give false positives, but none of the methods with a high rating for sensitivity appear to be unduly prone to this fault, particularly if we exclude tests on patients with leprosy, malaria, and perhaps tuberculosis.

Physicians in Massachusetts will be pleased to know that the Hinton test, which is the method routinely employed at the Wassermann Laboratory of the Massachusetts Department of Public Health and at a number of hospitals, ranks as one of the best methods in use.

Gratifying as these results must be to the serologist, it is evident that the physician cannot rely entirely on blood tests if he is to approach perfection in the diagnosis of syphilis, for approximately twenty per cent of the cases of untreated primary syphilis and fifteen per cent of those of late syphilis were not detected by any single method. Evidently much progress has been made but more is still possible.

AN UNJUST CONCEPTION OF MEDICINE AND PHYSICIANS

THE letter by a layman which appears on page 382 of this issue, presents the emotions and criticisms of a patient after release from a hospital. His reactions to the noise and his feeling that many hospitals are not well located will be endorsed by the medical profession. He probably does not know that the growth of a city places hospitals at a disadvantage in many particulars, but with great institutions such as exist in Boston the moving of them to better localities is impracticable under existing conditions. Many of the discomforts and even dangers incident to disease are very much overbalanced by modern hospitals. Full appreciation of our correspondent's complaints about noise exists with hospital authorities and staffs. But we may be excused for most positive condemnation of the last statement in the letter.

This shows either that the writer of the letter has not acquired his mental equilibrium or that he is wholly unappreciative of the attitude of the medical profession toward human suffering. Every sane-minded person deplors war and doctors are, for the most part, normal.

Organized medicine is striving to prevent hu-

man suffering and there is no alliance with war makers.

To include doctors with pigs of any sort is an insult which cannot be passed over without resentment.

MISCELLANY

THE NOMINATION OF DR. FRANCOIS R. MAHONY

Governor Curley has nominated Dr. Francis R. Mahony of Lowell for membership on the Board of Registration in Medicine. Action by the Council, according to custom is deferred for a week.

This is designed to fill the position occupied by Dr. Hovey of Springfield whose term has expired.

Since Dr. Mahony is a member of the Massachusetts Medical Society he is under the law not eligible for this position unless one of the three members of this board who are also members of the Massachusetts Medical Society shall have resigned.

CORRESPONDENCE

THE RELIABILITY OF THE HINTON TEST

The Commonwealth of Massachusetts
Department of Public Health

August 5 1935

Editor *New England Journal of Medicine*,

Dr. John Adams, Jr., of Boston believing that some confusion may have been created in the minds of many physicians by the substitution of the Hinton test for the Wassermann in the Department's laboratory has asked the Department to discuss the following types of cases

1 If there is no history of either acquired or congenital syphilis no clinical evidence of infection a negative spinal fluid negative blood Wassermann and Kahn, but a persistently positive blood Hinton is the diagnosis of syphilis justified and should the patient be treated intensively?

2 If a patient has received antisyphilitic treatment for a number of years for an old infection (adequate under Wassermann standards) is clinically free from infection, has a negative spinal fluid and negative blood Wassermann and Kahn, but a persistently positive blood Hinton should further treatment be given?

3 If a patient has early syphilis (primary or secondary) and has had continuous and energetic treatment for one or two years is clinically free from infection has a negative spinal fluid and all blood tests except the Hinton test are negative should the patient receive further treatment?

4 If a patient has a negative Hinton test, may central nervous system syphilis be excluded as a possibility?

These questions obviously may be stated briefly as one: How reliable is the Hinton test?

Physicians become confused by a new test because they compare it with the old without questioning the specificity of the old. That is like doubting the efficiency of a modern automobile because one has always driven a ten-year-old model. The recently discontinued Wassermann test was superior to the one originally done at the Department's laboratory. The newer precipitation tests notably the Kahn and Hinton are superior to the complement fixation test.

The recent evaluation of the outstanding blood tests by the United States Public Health Service places the Hinton test among the most nearly specific of any in use in this country. Specificity is measured both by the ability of a test to detect syphilis when it exists and its failure to give falsely positive results. The Hinton test not only ranked with the best in each of these values but was superior to the Kahn standard diagnostic test by 5.1 per cent in the detection of syphilis. The complement fixation tests on the whole, made a very poor showing in the detection of syphilis.

No laboratory test is infallible but it is apparent that the physician is far less likely to be in error if he depends upon the results of repeated Hinton tests than if he depends upon the less specific Wassermann in the same situation.

Physicians must also bear in mind that

1. The term "negative history" is by no means absolute and is much less reliable than repeated Hinton tests. Many patients known to have syphilis give no history of early lesions or other evidence pointing to infection either because they have observed none or have forgotten or wish to forget. Women, particularly miss the primary lesion because of its location in the vagina. Many an extra genital chancre has been missed or diagnosed as something else and forgotten. Innumerable infections have been discovered through blood tests alone.

2. The term "clinically negative" is not absolute and far less reliable than repeated Hinton tests. Physicians vary in their ability to detect visceral syphilis. Unless he is an experienced internist and has available a variety of laboratory aids (x-ray, electrocardiograph, etc.) he may fail to detect clinical evidence of infection, not to mention a slowly extending involvement which has not reached a clinically detectable stage.

3. The age of the patient must be taken into account as well as the duration of the infection. Given an infection of undetermined duration in a young person, it is safe to presume that it is sufficiently recent to deserve intensive and sustained treatment. Old people who have had syphilis for years, but who have no complaints or evidence of infection other than positive blood tests may do very well on mild intermittent treatment or on no treatment at all. Early syphilis or clinically active

syphilis deserves rigorous treatment, whatever the age of the patient. Syphilis in pregnant women or in women of child bearing age must have attention in any case.

4 A negative Hinton test does not exclude central nervous system syphilis as a possibility. However, the Hinton test will be positive in most cases of this form of the disease.

A patient with primary or secondary syphilis deserves a minimum of a year and a half of intensive treatment, without vacation, regardless of serology. Most syphilologists continue treatment thereafter, if necessary, until the blood serology has been negative for from six months to one year, under treatment. If the serology cannot be reversed after two to four years of treatment, and the spinal fluid is negative, further treatment may be modified according to the circumstances.

The treatment of long standing infections must be determined by the individual case, taking into account previous treatment, clinical activity, the age of the patient, pregnancy, etc. The objective is to keep the infection under control rather than to reverse the serology. The patient who has had a reasonable amount of treatment, but whose serology cannot be reversed to negative, must be handled as any "serologically-fast" case would be, even though the sensitive Hinton test is used. Blood tests are qualitative. They detect syphilis, but give no indication of its activity or of the extent of the infection. Although the future may bring better understanding of the serologically fast case, the best that can be said today is that any person with persistently positive blood has syphilis and must be watched, if not treated, with that in mind.

The Department suggests that physicians accept the Hinton test as one of the most specific tests available, in that it is falsely positive with extreme rarity and detects syphilis as well as, if not more frequently than, any other test in use. It should not be suspected of nonspecificity by comparison with the Wassermann or any other test. Its specificity has been studied against known infections and known freedom from infection for many years. The Department adopted it then, only after consultation with many syphilologists who had had experience with it.

The Department wishes to express its appreciation to Drs William P Boardman, Austin W Cheever, Walter T Garfield, Rudolph Jacoby, E Lawrence Oliver, C Morton Smith, and Francis M Thurmon, for their advice and to Dr John Adams, Jr, for asking the questions which have given the Department this opportunity for discussing the Hinton test.

Yours truly,

N A. NELSON, M D, *Assistant Director,*
Division of Communicable Diseases

A LAYMAN PUTS A QUESTION TO THE MEDICAL PROFESSION

Lying in bed five weeks or more in a room of one of the most highly developed hospitals of New England, in the course of which time I was rolled into the operating room twice for those intrusions by a surgeon into the recesses of my anatomy which are called "major operations", I added a great deal to my high previous regard for hospitals, nurses and doctors.

One becomes thoroughly aware of the existence of two social worlds — the world of the well and the world of the sick. The world of the well was going past the windows of that hospital in a torrent of devastating noise. It seemed incredible that a great building full of sick people should be so disregarded by the city authorities.

Why should not traffic be diverted so as to leave hospitals with some degree of quiet? And certainly quiet is a therapeutic resource and hastens recovery by inducing sleep at night and reducing nervous tension all day. You are rolled out on the balcony for air and change of scene. The air is tainted with coal and oil gasses, and the scene is a crawling horror of autos emitting their characteristic obscenities.

The society of the sick takes what is handed to it. We have no choice. We belong to "Les Misérables", and are grateful that time passes and the day of our release does draw nearer—provided, as the orderly remarked when I was going to the operating room, you have a return ticket.

However, the question which pressed in upon me more and more as I experienced the trained mercies of that place and the really tender, if relentless, offices of the doctors, was this:

In the event of war all these same highly skilled services and intricate equipment for comfort are devoted to cases of *manufactured sickness*.

People who would otherwise be well, in fact, the most healthy and vigorous part of the population of the nations involved, are, due to the egotisms, the antipathies, greeds and vindictiveness of statesmen and politicians, compelled to become cases for hospitals and doctors—and by the thousands daily.

Hospitals and nurses and doctors are provided in advance. Everything is arranged to receive the flood of *manufactured sick*. And presently here they come—by the train load, and the work begins, incessant, overwhelming, heartbreaking.

The amazing thing is this: there never has been a protest from the medical profession as such, from any association of doctors, against this manufacturing of sickness.

One wonders why. Do they like it, then? Do they rejoice in the added experience, in the enormous variety of wounds and diseases? Is it all a kind of medical and surgical orgy in which they feel peculiarly intoxicated with self forgetfulness and the practice of their art wholesale?

Would you not think that doctors would be among

the very first to resent these by products of hostility forced on their attention?

But no there is no recorded instance which I have been able to discover of a protest against war against manufactured sickness by any medical association in America.

Can that be explained by doctors without incrimination and some sense of shame? And is it possible that we must remain content with the spectacle of the medical profession prostituted in this manner—following the handwagon of the politician and the silk-hatted gentlemen of diplomacy into the big tent and there compelled to perform while the whip cracks?

For you may say all that can be said about the devotion and the exhilaration of self forgetfulness and about the experience gained and stored up for future use—this certainly is casting pearls before swine

For war makers are just that. They are not only pigs but they have the ugliest trait of the worst pigs—namely they devour their own progeny.

It does seem strange, to a man in a hospital at any rate that doctors should make common cause with such people. But they do

SOME HINTS AIDING IN THE DIAGNOSIS OF ANTERIOR POLIOMYELITIS BEFORE THE PARALYTIC STAGE

The present epidemic of infantile paralysis has focused the attention of the entire medical profession upon this disease. The anxiety of parents calls the average practitioner to see many cases that have symptoms which might possibly be those of this dangerous malady.

While I do not make pretensions of being well informed on the subject, I have had occasion to delve into the literature in order to refresh my memory. There should be an eagerness on the part of every physician to diagnose this disease before the paralysis sets in. The fault is to a great extent acquainted with some symptoms and certainly the average parent can make a diagnosis when the child loses the use of some member. I should like to present a brief outline of the disease in its preparalytic stage in order that my brother physicians may make a hasty résumé. I realize that busier men may not have a similar opportunity to review the description of the disease which is usually very lengthy. I present only the symptoms of the preparalytic stage and a few hints to help in diagnosis.

The incubation period is from four to eight days. A ten-day period of isolation should be imposed on all contacts. How long the patient is infectious is unknown but modern practice is to insist on isolation for three weeks after nasal discharges have disappeared.

The following are the points to be noted

1. Fanciful reddening
2. Fever—(101-103)

3. Headache
4. Vomiting
5. Diarrhea.
6. Convulsions—especially in young children.
7. Tenderness of muscles and hyperaesthesia.
8. Irritability
9. Intolerance of handling
10. Kernig's sign.

After a glance at the above symptoms it will be apparent to the doctor that some of them, especially the first six are common to other childhood diseases. The latter four are peculiar to diseases involving the central nervous system. They are difficult to evaluate particularly in younger children who resent the handling of the examiner. A good test for infants is to set them on a flat surface (a table for example) with legs extended before them. The patient who is infected will put his hands on the table to support his spinal column which is painful and is held rigid. The child will also elevate the shoulders as though the back were sore very much like a person whose back is sunburned. This will also indicate a stiffness of the neck a valuable symptom, as this is difficult to ascertain in young children. One must be careful that the stiffness is not caused by cervical adenitis attending some simple pharyngeal infection.

Kernig's sign will be found to be very often more or less developed. This will serve to differentiate the disease and others that may simulate it. It is carried out with the child on its back the thigh is flexed on the abdomen and the leg is extended. A positive sign is present when there is resistance on the part of the hamstrings—when any extension of the knee-joint is difficult, and full extension is impossible.

If any or all of these symptoms are present to such an extent that the physician entertains a reasonable suspicion, lumbar puncture is necessary. The physician should do this himself if he is equipped or remove the child to a place where it can be correctly carried out. Upon insertion of the needle increased pressure will usually be found if the disease is present. Cells that number more than ten or fifteen per cubic millimeter certainly point to a correct diagnosis. Polys may exceed 80 per cent. On repeated punctures they rapidly change to mononuclears. Later there is a gradual decrease in cells and an increase in protein. The sugar is little disturbed, a valuable point in differentiating tubercular meningitis which has a sharp decrease.

These few suggestions are offered in a hope that they may prove valuable to busy practitioners some of whom will undoubtedly be called to see some young sufferer. They may be helpful in making a speedy diagnosis, thereby promptly bringing to the patient the best available treatment.

Sincerely yours,

FRED L. CAMPBELL, M.D.

CORRECTION OF A REVIEW OF "TEN YEARS OF RURAL HEALTH WORK IN RUTHERFORD COUNTY, TENNESSEE"

The Commonwealth Fund
41 East 57th Street
New York City

August 13, 1935

Editor, *New England Journal of Medicine*,

I regret the necessity of calling to your attention certain errors of fact in the review of the booklet "Ten Years of Rural Health Work in Rutherford County, Tennessee", recently published by the Commonwealth Fund. This review appeared in the July 11, 1935 issue of the *Journal*.

It seems quite apparent that the reviewer was somewhat casual in his reading of the book. His first error is the location of the county, which he twice puts in Kentucky though the title clearly and correctly located it in Tennessee. Further on, the reviewer has taken a two paragraph summary of the situation prior to the demonstration, given on the bottom of page 4 and the top of page 5, which clearly dates the conditions as prior to 1924 and quotes from it implying that it describes the conditions "at the end of the demonstration".

Although the Commonwealth Fund welcomes comments and criticisms that are pertinent and based on facts, the misstatements of fact, and an evaluation of the publication far out of line with that of other reviewers, lead indubitably to the impression that the reviewer has been careless in his reading and made little effort to understand the objective of the book, or the facts presented in it, before writing his review.

In fairness to the many prominent public health workers who were engaged in carrying out this enterprise, as well as to the Commonwealth Fund who sponsored it, I shall be very glad, provided it be consistent with the policy of your *Journal*, if some correction of this unfortunate review may be published.

Sincerely yours,

BARRY C SMITH.

BOOK REVIEWS

Diseases of the Nervous System. A textbook of Neurology and Psychiatry. Smith Ely Jelliffe and William A. White. Sixth Edition, 1935. 1175 pp. Philadelphia: Lea & Febiger.

The sixth edition of this important text includes all important contributions to neurology and psychiatry, of sufficient weight to warrant inclusion, which have appeared since the last edition. The book has been revised, rewritten and significant additions to the text are included. In order that the book should not be increased in bulk, the pages are correspondingly enlarged.

New methods of examinations of neurological and psychiatric patients are discussed at length. Sections dealing with the hypothalamic region in connection with metabolic studies are very complete. The surgery of the sympathetic nervous system and its wide application receive adequate mention. There is a wealth of new material dealing with interpretation of the activity of the symbolic systems.

Neurology and psychiatry as specialties are carefully related to general medicine by the authors and provide a basis for extensive integration of these fields. The book deals in the first section with The Physico-Chemical Systems, or the Neurology of Metabolism, in the second with the Sensorimotor Systems and in the third with the Psychological or Symbolic Systems. Among the topics which are outstanding for their careful consideration are the following: pachymeningitis interna hemorrhagica, syringomyelia, cerebellar syndromes and the treatment of neuroses and psychoses. The volume is worth having within easy reach whether the owner is specialist or general practitioner.

A New Bibliography from Argentina

In 1933 there was formed a Committee of Bibliographical Information of the Medical Sciences of Buenos Aires. This Committee has undertaken to collect and publish as complete a bibliography as possible of the articles on medicine and the allied sciences published in Argentina. The first series consists of bibliographies dealing with Pediatrics and Puericulture, Biology and Physiology, Toxicology and Pharmacy and Chemistry. Some of the articles are abstracted while others are reported only by title.

HERNIATION OR RUPTURE OF THE INTERVERTEBRAL DISC INTO THE SPINAL CANAL*

Report of Thirty Four Cases

BY WILLIAM JASON MIXTER, M.D.† AND JAMES B. AYER, M.D.†

IN the course of a good many years' experience with tumors of the spinal cord we had become familiar with the so-called enchondroma of the intervertebral disc. We had also become accustomed to the statement of the pathologist that he supposed the tumor must be an enchondroma, but that on section it looked like normal intervertebral disc. About three years ago Dr. Joseph Barr of the Orthopedic Department of the Massachusetts General Hospital impressed upon us the idea that these masses were identical with the nodules described by Schmorl.¹⁷ It is interesting to note that Schmorl states quite positively that these nodules seldom if ever cause neurological symptoms. Investigation of the literature and our own cases resulted in a preliminary report by Mixter and Barr¹⁴ of nine teen cases largely from the records of the Massachusetts General Hospital.

As far as we can determine rupture and extrusion of the intervertebral disc into the spinal canal was first described in 1911 independently by Goldthwait¹⁰ in this country and by Middleton and Teacher¹⁸ in England, but these contributions seem to have been forgotten. At any rate, the subject received scant attention for a good many years. In the meantime reports of enchondroma or echondroma of the intervertebral disc began to appear. Elsberg⁷ in 1916 mentions the subject and states that Oppenheim had observed such a case. Olymer, Mixter and Mella³ in 1921 note a similar case. Numerous other reports by Elsberg⁸, Stookey¹⁹, Bncy², Petit Dutailis and Alajouanine¹⁶, Adson¹ and others came into the literature. Dandy⁴ in 1929 reported two cases from which he had removed loose cartilaginous fragments protruding into the spinal canal. He considered them undoubtedly traumatic in origin. Elsberg⁹ in 1931 again described these growths. The subject has been discussed more recently by Alpers, Grant and Yaskin², who collected a large group of cases of chondroma from the literature up to 1933.

From the Neurological Department and the Neurosurgical Department of the Massachusetts General Hospital.

†Mixter, William Jason—Visiting Surgeon, Massachusetts General Hospital, Ayer, James B.—Professor of Neurology Harvard University Medical School. For record and addresses of author see "This Week's Issue," page 43.

Pect and Echols¹⁵ report two cases of herniation of the nucleus pulposus observed at operation. Maurice¹² in 1933, from a study of the literature, came to the conclusion, although he had observed no cases himself that many of the so-called enchondromata and Schmorl's nodules were identical. We had come to the same conclusion about the same time from clinical observations.

In our earlier cases, as in the references quoted above, the differential diagnosis lay between tumor and ruptured disc. We have been unable to find in the literature any group of cases in which the diagnosis was made in the absence of pronounced neurological signs and in which the differential diagnosis lay between low back strain of one sort or another and rupture of the intervertebral disc. The considerable number of such cases of this type which we are now able to report is the main reason for this communication.

In the eighteen months since the report of Mixter and Barr¹⁴ we have observed fifteen additional cases. Our present paper is based on a study of the whole series of thirty four cases, proved at operation, twenty three of which were into the lumbosacral canal. Since 1912, in addition, there have been observed at the Massachusetts General Hospital six cases of true cartilaginous neoplasm of the spine. As these present an entirely different picture both clinically and pathologically from rupture of the intervertebral disc, they are omitted from this paper.

The disc specimens obtained at operation vary considerably as to the amount of annulus and nucleus present.⁶ Dr. Charles Knirk, neuropathologist at the Massachusetts General Hospital, has reviewed many of these specimens and feels that both nucleus and annulus are represented in most. At operation one is impressed with the fibrous character of the extruded fragment. We believe, therefore, that the term

*The normal intervertebral disc is composed of two quite different cartilaginous structures. The annulus fibrosus is as its name implies a ring like structure of fibro-cartilage. Within this ring is a soft lenticular body the nucleus pulposus. This structure is 75 per cent water and contains cellular elements from the notochord in a rather gelatinous matrix in which the fibrils are found.

herniation or rupture of the intervertebral disc is more descriptive than "prolapse of the nucleus pulposus" as coined by Schmorl (Fig 1)

HERNIATION OF DISC INTO LUMBOSACRAL CANAL

Incidence Of the twenty-three patients with this type of lesion, only four were women. At the time of operation the youngest was twenty years, the oldest sixty-four. The ages thirty to

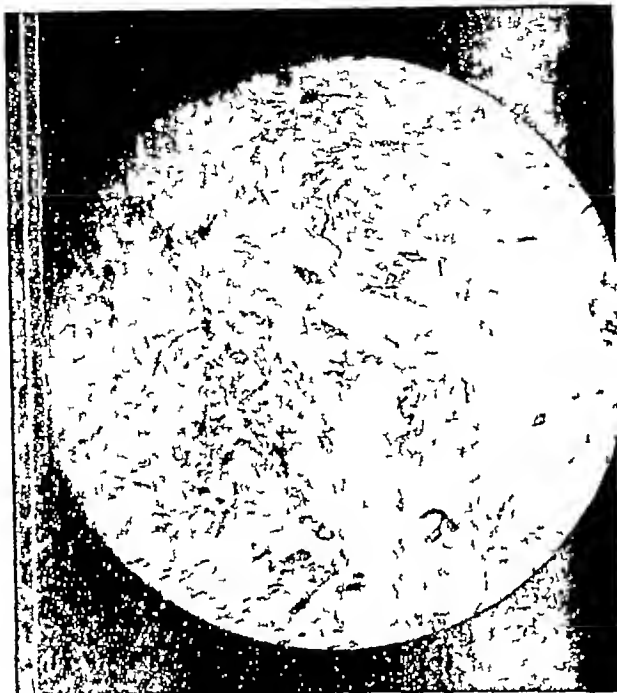

FIG 1 Microphotograph from specimen obtained at operation L C M G H No 325587. Material from annulus on the left and from nucleus on the right.

fifty furnished two-thirds of all the cases. No racial disposition was indicated.

Etiology A satisfactory history of antecedent trauma was obtained from fourteen patients and specifically denied by five. In only seven (one-third of all the cases) did it seem certain that an accident was followed immediately by the symptoms for which later the operation was performed.

It would be of interest to correlate as factors in causing rupture of a disc the physical development, body mechanics and nutritional state of the patients. This study, however, was not made. All we can say is that the work engaged in at the time of the rupture represented a wide variety of indoor and outdoor activity and that the individuals afflicted were not conspicuous for under- or over-development, nor were they otherwise, with one exception, chronic invalids.

As a typical example of the group under discussion the following case history is given:

CASE 1 D S No 342673 M G H, a man of slight build, forty-four years old, machinist in a cotton mill, complains of low back pain of two years' duration, radiating to the right but-

tock and down the posterior aspect of the right thigh and leg. There is no pain elsewhere and no difficulty with sphincters. The present symptoms are similar to pain experienced six years ago which came on suddenly when lifting a heavy bale of cloth, necessitating bed rest for five weeks. In the intervening four years he has been well and active.

He stands and walks with a list forward and to the right, bends body forward with caution and associated flexion of the right knee. There is tenderness on pressure over the right sacro-iliac joint and increased pain in this region on straight leg raising which is greatly limited on this side. Although gluteus, hamstrings and calf appear a little softer and smaller on the right than on the left side, no appreciable weakness is observed, and sensory loss is limited to hypaesthesia of skin over the external aspect of the lower right leg. The sole reflex abnormality is absence of the right Achilles jerk.

Combined lumbar puncture with needles at L1-2 and L5-S1 spaces shows no block, both fluids clear, colorless and in every respect normal except for elevation of protein, 59 mg and 67 mg respectively. (It is almost certain that both needles were above the tumor.)

X-ray after lipiodol injection into L1-2 space shows a concave defect in the lipiodol column outlining a rounded mass in the canal on the right side between the fifth lumbar vertebra and the sacrum.

At operation a piece of ruptured disc was found at the place indicated by lipiodol, and observed to press directly on the fifth lumbar root.

Symptoms and Signs As the site of the lesion in our cases varied so little, and the size of the herniated portion of the disc was found to be so uniform, it is not surprising that symptoms and signs should be similar. It is more in the course of the disease than in the nature of symptoms that we find individual differences.

Sensory Symptoms and Signs Pain was the first symptom in every case, and it was for relief of pain that all except two sought relief, in two only, disability was of prime importance. The pain was usually described as an ache in the low back, usually just to one side or the other, becoming paroxysmal on turning, stooping, coughing and sneezing, whereupon it would radiate outward over the buttock and down the back of the thigh, and at times the back of the leg also. Not infrequently the pain commenced in the mid-line and radiated down the back of both thighs, but unilateral distribution was the rule, even though symptoms had lasted many months. Pain in the perineum also was present in three patients. In only one was the pain referred to the anterior aspect of the thigh.

To minimize the pain, many patients assumed a slight stoop in walking and standing, and on examination the lumbar muscles were found in protective spasm. Tenderness even on gentle percussion over the low spine, lumbosacral ligaments and sacro-iliac joint was commonly present, and yet rarely was the sciatic nerve tender on deep palpation. Notwithstanding, straight

leg raising in the supino position was greatly restricted on the affected side (and also to a less extent on the unaffected side)

In spite of very great pain, little objectively determined sensory loss was the rule, and only rarely was bilateral saddle anesthesia obtained

Numbness and paresthesiae frequently alternated with pain or were substituted for it.
